Genetic Programming as a Means for Programming Computers by Natural Selection

JOHN R. KOZA<br>Computer Science Department, Stanford University, Stanford, California 94305. Koza@CS.Stanford.Edu, 415-941-0336

Many seemingly different problems in machine learning, artificial intelligence, and symbolic processing can be viewed as requiring the discovery of a computer program that produces some desired output for particular inputs. When viewed in this way, the process of solving these problems becomes equivalent to searching a space of possible computer programs for a highly fit individual computer program. The recently developed genetic programming paradigm described herein provides a way to search the space of possible computer programs for a highly fit individual computer program to solve (or approximately solve) a surprising variety of different problems from different fields. In genetic programming, populations of computer programs are genetically bred using the Darwinian principle of survival of the fittest and using a genetic crossover (sexual recombination) operator appropriate for genetically mating computer programs. Genetic programming is illustrated via an example of machine learning of the Boolean 11-multiplexer function, symbolic regression of the econometric exchange equation from noisy empirical data, the control problem of backing up a tractor-trailer truck, the classification problem of distinguishing between two intertwined spirals., and the robotics problem of controlling an autonomous mobile robot to find a box in the middle of an irregular room and move the box to the wall.
Hierarchical automatic function definition enables genetic programming to define potentially useful functions automatically and dynamically during a run - much as a human programmer writing a complex computer program creates subroutines (procedures, functions) to perform groups of steps which must be performed with different instantiations of the dummy variables (formal parameters) in more than one place in the main program. Hierarchical automatic function definition is illustrated via the machine learning of the Boolean 11-parity function.

Keywords: Genetic programming, genetic algorithm, crossover, hierarchical automatic function definition, symbolic regression, Boolean 11-multiplexer, econometric exchange equation, truck backer-upper, intertwined spirals, box moving robot, Boolean 11-parity.

## 1. Introduction and Overview

Computer programs are among the most complex and intricate structures created by man. Computer programs are usually written line-by-line by applying human knowledge and intelligence to the problem at hand. Writing a computer program is usually difficult.

Indeed, one of the central questions in computer science (attributed to Arthur Samuel in the 1950s) is

How can computers learn to solve problems without being explicitly programmed? In other words, how can computers be made to do what is needed to be done, without being told exactly how to do it?

In the natural world, complex and intricate structures do not arise via explicit design and programming or from the application of human intelligence. Instead, complex and successful organic structures evolve over a period of time as the consequence of Darwinian natural selection and the creative effects of sexual recombination (genetic crossover) and mutation. Complex structures evolve in nature as a consequence of a fitness metric applied by the problem environment because structures that are more fit in grappling with their environment survive and reproduce at a higher rate.

The question arises as to whether an analog of natural selection and genetics can be applied to the problem of creating a program that enables a computer to solve a problem. That is, can complex computer programs be created, not via human intelligence, but by applying a fitness measure appropriate to the problem environment?

Such a process of genetically breeding of computer programs might start with a primordial ooze consisting of a population of hundreds or thousands of randomly created computer programs of various randomly determined sizes and shapes. In such a process, each program in the population would be observed as it tries to grapple with its environment - that is, to solve the problem at hand. A value would then be assigned to each program reflecting how fit it is in solving the problem at hand. We might then allow a program in the population to survive to a later generation of the process with a probability proportionate to its observed fitness. Additionally, we might also select pairs of programs from the population with a probability proportionate to their observed fitness and create new offspring by recombining subprograms from them at random. We would apply the above steps to the population of programs over a number of generations.

Anyone who has ever written and debugged a computer program and has experienced their brittle, highly non-linear, and perversely unforgiving nature will probably be understandably skeptical about the proposition that the biologically motivated process sketched above could possibly produce a useful computer program. However, in this article, we will present a number of examples from various fields supporting the surprising and counter-intuitive notion that computers can indeed by programmed by means of natural selection. We will show, via examples, that the recently developed genetic programming paradigm provides a way to search the space of all possible programs to find a function which solves, or approximately solves, a problem.

## 2. Background on Genetic Algorithms and Genetic Programming

John Holland's pioneering 1975 Adaptation in Natural and Artificial Systems described how the evolutionary process in nature can be applied to artificial systems using the genetic algorithm operating on fixed length character strings [Holland 1975]. Holland demonstrated that a population of fixed length character strings (each representing a proposed solution to a problem) can be genetically bred using the Darwinian operation of fitness proportionate reproduction and the genetic operation of recombination. The recombination operation combines parts of two chromosome-like fixed length character strings, each selected on the basis of their fitness, to produce new offspring strings. Holland established, among other things, that the genetic algorithm is a near optimal approach to adaptation in that it maximizes expected overall average payoff when the adaptive process is viewed as a multi-armed slot machine problem requiring an optimal allocation of future trials given currently available information. The genetic algorithm has proven successful at searching nonlinear multidimensional spaces in order to solve, or approximately solve, a wide variety of problems [Goldberg 1989, Davis 1987, Davis 1991, Davidor 1991, Michalewicz 1992]. Recent conference proceedings provide an overview of current work in the field [Schaffer 1989, Forrest 1990, Belew and Booker 1991, Rawlins 1991, Meyer and Wilson 1991, Schwefel et al. 1991, Langton et al. 1992, Whitley 1992].

Representation is a key issue in genetic algorithm work because genetic algorithms directly manipulate a coded chromosomal representation of the problem. The representation scheme can therefore severely limit the window by which the system observes its world. On the other hand, the use of fixed length character strings has permitted Holland and others to construct a significant body of theory as to why genetic algorithms work. Much of this theoretical analysis depends on the mathematical tractability of the fixed length character strings as compared with mathematical structures that are more complex and comparatively less susceptible to theoretical analysis. The need for increasing the complexity of the structures undergoing adaptation using the genetic algorithm has been reflected by considerable work over the years in that direction [Smith 1980, Cramer 1985, Holland 1986, Holland et al. 1986, Wilson 1987a, Wilson 1987b, Fujiki and Dickinson 1987, Goldberg et al 1989].

For many problems in machine learning and artificial intelligence, the most natural representation for a solution is a computer program (i.e., a
hierarchical composition of primitive functions and terminals) of indeterminate size and shape, as opposed to character strings whose size has been determined in advance. It is difficult, unnatural, and overly restrictive to attempt to represent hierarchies of dynamically varying size and shape with fixed length character strings.

Genetic programming provides a way to find a computer program of unspecified size and shape to solve, or approximately solve, a problem. The book Genetic Programming: On the Programming of Computers by Means of Natural Selection [Koza 1992a] describes genetic programming in detail. A videotape visualization of applications of genetic programming can be found in the Genetic Programming: The Movie [Koza and Rice 1992]. See also Koza [1992b].

## 3. Overview of Genetic Programming

Genetic programming continues the trend of dealing with the problem of representation in genetic algorithms by increasing the complexity of the structures undergoing adaptation. In particular, the individuals in the population in genetic programming are hierarchical compositions of primitive functions and terminals appropriate to the particular problem domain. The set of primitive functions used typically includes arithmetic operations, mathematical functions, conditional logical operations, and domainspecific functions. The set of terminals used typically includes inputs appropriate to the problem domain and various numeric constants.

The compositions of primitive functions and terminals described above correspond directly to the computer programs found in programming languages such as LISP (where they are called symbolic expressions or S-expressions). An S-expression can be represented as a rooted, point-labeled tree with ordered branches in which the root and other internal points of the tree are labeled with functions and in which the external points of the tree are labeled with terminals. In fact, these compositions correspond directly to the parse tree that is internally created by the compilers of most programming languages. Thus, genetic programming views the search for a solution to a problem as a search in the space of all possible compositions of functions that can be recursively composed of the available primitive functions and terminals.

Of course, virtually any problem in artificial intelligence, symbolic processing, and machine learning can be viewed as requiring discovery of a computer program that produces some desired output for particular inputs. The process of solving these problems can be reformulated as a search for a highly fit individual computer program in the space of
possible computer programs. When viewed in this way, the process of solving these problems becomes equivalent to searching a space of possible computer programs for the fittest individual computer program. In particular, the search space is the space of all possible computer programs composed of functions and terminals appropriate to the problem domain. Genetic programming provides a way to search for this fittest individual computer program.

In genetic programming, populations of hundreds or thousands of computer programs are genetically bred. This breeding is done using the Darwinian principle of survival and reproduction of the fittest along with a genetic recombination (crossover) operation appropriate for mating computer programs. As will be seen, a computer program that solves (or approximately solves) a given problem may emerge from this combination of Darwinian natural selection and genetic operations.

Genetic programming starts with an initial population of randomly generated computer programs composed of functions and terminals appropriate to the problem domain. The functions may be standard arithmetic operations, standard programming operations, standard mathematical functions, logical functions, or domain-specific functions. Depending on the particular problem, the computer program may be Boolean-valued, integer-valued, real-valued, complex-valued, vector-valued, symbolic-valued, or multiple-valued. The creation of this initial random population is, in effect, a blind random search of the search space of the problem.

Each individual computer program in the population is measured in terms of how well it performs in the particular problem environment. This measure is called the fitness measure.

The nature of the fitness measure varies with the problem. For many problems, fitness is naturally measured by the error produced by the computer program. The closer this error is to zero, the better the computer program. If one is trying to find a good randomizer, the fitness of a given computer program might be measured via entropy. The higher the entropy, the better the randomizer. If one is trying to recognize patterns or classify examples, the fitness of a particular program might be the number of examples (instances) it handles correctly. The more examples correctly handled, the better. In a problem of optimal control, the fitness of a computer program may be the amount of time or fuel or money required to bring the system to a desired target state. The smaller the amount of time or fuel or money, the better. For some problems, fitness may consist of a combination of factors such as correctness, parsimony, or efficiency.

Typically, each computer program in the population is run over a number of different fitness cases so that its fitness is measured as a sum or an average over a variety of representative different situations. These fitness cases sometimes represent a
sampling of different values of an independent variable or a sampling of different initial conditions of a system. For example, the fitness of an individual computer program in the population may be measured in terms of the sum of the squares of the differences between the output produced by the program and the correct answer to the problem. This sum may be taken over a sampling of different inputs to the program. The fitness cases may be chosen at random or may be structured in some way.

The computer programs in generation 0 will have exceedingly poor fitness. Nonetheless, some individuals in the population will turn out to be somewhat fitter than others. These differences in performance are then exploited.

The Darwinian principle of reproduction and survival of the fittest and the genetic operation of sexual recombination (crossover) are used to create a new offspring population of individual computer programs from the current population of programs.

The reproduction operation involves selecting on the basis of fitness (i.e., the fitter the program, the more likely it is to be selected), a computer program from the current population of programs, and allowing it to survive by copying it into the new population.

The genetic process of sexual reproduction between two parental computer programs is used to create new offspring computer programs from two parental programs selected on the basis of fitness. The parental programs are typically of different sizes and shapes. The offspring programs are composed of subexpressions (subtrees, subprograms, subroutines, building blocks) from their parents. These offspring programs are typically of different sizes and shapes than their parents.

Intuitively, if two computer programs are somewhat effective in solving a problem, then some of their parts probably have some merit. By recombining randomly chosen parts of somewhat effective programs, we may produce new computer programs that are even fitter in solving the problem.

For example, consider the following computer program (LISP symbolic expression):
(+ (* 0.234 Z$) ~(-\mathrm{X} \mathrm{0.789))}$,
which we would ordinarily write as

$$
0.234 \mathrm{Z}+\mathrm{X}-0.789
$$

This program takes two inputs ( X and Z ) and produces a floating point output. In the prefix notation used, the multiplication function $*$ is first applied to the terminals 0.234 and z to produce an intermediate result. Then, the subtraction function - is applied to the terminals X and 0.789 to produce a second intermediate result. Finally, the addition function + is applied to the two intermediate results to produce the overall result.

Also, consider a second program:
$(*(* Z Y)(+Y(* 0.314 \mathrm{Z})))$,
which is equivalent to

ZY (Y + 0.314 Z).
In figure 1, these two programs are depicted as rooted, point-labeled trees with ordered branches. Internal points (i.e., nodes) of the tree correspond to functions (i.e., operations) and external points (i.e., leaves, endpoints) correspond to terminals (i.e., input data). The numbers beside the function and terminal points of the tree appear for reference only.

$0.234 \mathrm{Z}+\mathrm{X}-0.789$

Figure 1 Two Parental computer programs.
The crossover operation creates new offspring by exchanging sub-trees (i.e., sub-lists, subroutines, subprocedures) between the two parents.

Assume that the points of both trees are numbered in a depth-first way starting at the left. Suppose that the point number 2 (out of 7 points of the first parent) is randomly selected as the crossover point for the first parent and that the point number 5 (out of 9 points of the second parent) is randomly selected as the crossover point of the second parent. The crossover points in the trees above are therefore the * in the first parent and the + in the second parent. The two crossover fragments are the two sub-trees shown in figure 2.

0.234 Z

Figure 2 Two Crossover Fragments.
These two crossover fragments correspond to the underlined sub-programs (sub-lists) in the two parental computer programs. The two offspring resulting from crossover are
$(+\underline{(+\mathrm{Y}(* 0.314 \mathrm{Z}))}(-\mathrm{X} 0.789))$
and
(* (* Z Y) (* 0.234 Z$)$ ).
The two offspring are shown in figure 3 .

Figure 3 Two Offspring.
Thus, crossover creates new computer programs using parts of existing parental programs. Because entire sub-trees are swapped, this crossover operation always produces syntactically and semantically valid programs as offspring regardless of the choice of the two crossover points. Because programs are selected to participate in the crossover operation with a probability proportional to fitness, crossover allocates future trials to areas of the search space represented by programs containing parts from promising programs.

After the operations of reproduction and crossover are performed on the current population, the population of offspring (i.e., the new generation) replaces the old population (i.e., the old generation).

Each individual in the new population of computer programs is then measured for fitness, and the process is repeated over many generations.

At each stage of this highly parallel, locally controlled, decentralized process, the state of the process will consist only of the current population of individuals. The force driving this process consists only of the observed fitness of the individuals in the current population in grappling with the problem environment.

As will be seen, this algorithm will produce populations of computer programs which, over many generations, tend to exhibit increasing average fitness in dealing with their environment. In addition, these populations of computer programs can rapidly and effectively adapt to changes in the environment.

Typically, the best individual that appeared in any generation of a run (i.e., the best-so-far individual) is designated as the result produced by genetic programming.

The hierarchical character of the computer programs that are produced is an important feature of genetic programming. The results of genetic programming are inherently hierarchical. In many cases the results produced by genetic programming are default hierarchies, prioritized hierarchies of tasks, or hierarchies in which one behavior subsumes or suppresses another.

The dynamic variability of the computer programs that are developed along the way to a solution is also an important feature of genetic programming. It would be difficult and unnatural to try to specify or restrict the size and shape of the eventual solution in
advance. Moreover, advance specification or restriction of the size and shape of the solution to a problem narrows the window by which the system views the world and might well preclude finding the solution to the problem at all.

Another important feature of genetic programming is the absence or relatively minor role of preprocessing of inputs and postprocessing of outputs. The inputs, intermediate results, and outputs are typically expressed directly in terms of the natural terminology of the problem domain. The computer programs produced by genetic programming consist of functions that are natural for the problem domain.

Finally, the structures undergoing adaptation in genetic programming are active. They are not passive chromosomal encodings of the solution to the problem. Instead, given a computer on which to run, the structures in genetic programming are active program structures that are capable of being executed in their current form.

In summary, genetic programming breeds computer programs to solve problems by executing the following three steps:
(1) Generate an initial population of random computer programs composed of the primitive functions and terminals of the problem.
(2) Iteratively perform the following sub-steps until the termination criterion for the run has been satisfied:
(a) Execute each program in the population so that a fitness measure indicating how well the program solves the problem can be computed for the program.
(b) Create a new population of programs by selecting program(s) in the population with a probability based on fitness (i.e., the fitter the program, the more likely it is to be selected) and then applying the following primary operations:
(i) Reproduction: Copy an existing program to the new population.
(ii) Crossover: Create two new offspring programs for the new population by genetically recombining randomly chosen parts of two existing programs.
(3) The single best computer program in the population produced during the run is designated as the result of the run of genetic programming. This result may be a solution (or approximate solution) to the problem.
Figure 4 is a flowchart for genetic programming. The index i refers to an individual in the population of size $M$. The variable GEN is the number of the current generation. The box labeled "Evaluate fitness of each individual in the population" typically consumes the vast majority of computer resources.

Figure 4 Flowchart for genetic programming.
In the remainder of this article, we illustrate genetic programming with several examples chosen to illustrate various different categories of problems, namely

- symbolic regression of a Boolean-valued function,
- symbolic regression of noisy numeric-valued empirical data,
- a multidimensional control problem,
- a classification problem,
- a robotics problem, and
- a problem employing hierarchical automatic function definition.

## 4. Symbolic Regression-11-Multiplexer

The problem of symbolic function identification (symbolic regression) requires developing a composition of terminals and functions that can return the correct value of the function after seeing a finite sampling of combinations of the independent variable associated with the correct value of the dependent variable. The problem of machine learning of a

Boolean function is a special case of symbolic regression in which the independent variables are Boolean-valued, the functions being composed are Boolean functions, and the dependent variable is Boolean-valued.

The problem of learning the Boolean 11multiplexer function will serve to show the interplay in genetic programming of

- the genetic variation inevitably created in the initial random generation,
- the small improvements for some individuals in the population via localized hill-climbing from generation to generation,
- the way particular individuals become specialized and able to correctly handle certain sub-cases of the problem (case-splitting),
the creative role of crossover in recombining valuable parts of more fit parents,
how the nurturing of a large population of alternative solutions to the problem (rather than a single point in the solution space) helps avoid false peaks in the search for the solution to the problem, and
that it is not necessary to determine in advance the size and shape of ultimate solution or the intermediate results that may contribute to the solution.
The input to the Boolean N -multiplexer function consists of $k$ address bits $a_{i}$ and $2^{k}$ data bits $d_{i}$, where $\mathrm{N}=\mathrm{k}+2^{\mathrm{k}}$. That is, the input consists of the $\mathrm{k}+2^{\mathrm{k}}$ bits

$$
\mathrm{a}_{\mathrm{k}-1}, \ldots, \mathrm{a}_{1}, \mathrm{a}_{0}, \mathrm{~d}_{2} \mathrm{k}_{-1}, \ldots, \mathrm{~d}_{1}, \mathrm{~d}_{0}
$$

The value of the Boolean multiplexer function is the Boolean value ( 0 or 1 ) of the particular data bit that is singled out by the k address bits of the multiplexer. For example, for the Boolean 11multiplexer (where $\mathrm{k}=3$ ), if the three address bits $a_{2} a_{1} a_{0}$ are 110 , the multiplexer singles out data bit number 6 (i.e., $\mathrm{d}_{6}$ ) to be the output of the multiplexer.
Figure 5 shows a Boolean 11-multiplexer with an input of 11001000000 and the corresponding output of 1.

Figure 5 Boolean 11-multiplexer

There are five major steps in preparing to use genetic programming, namely determining
(1) the set of terminals,
(2) the set of primitive functions,
(3) the fitness measure,
(4) the parameters for controlling the run, and
(5) the method for designating a result and the criterion for terminating a run.
The first major step in preparing to use genetic programming is the identification of the set of terminals that will be available for constructing the computer programs (S-expressions) that will try to solve the problem. This choice is especially straightforward for this problem. The terminal set for this problem consists of the 11 inputs to the Boolean 11multiplexer. Thus, the terminal set T for this problem consists of

$$
\mathcal{T}=\{\mathrm{A} 0, \mathrm{~A} 1, \mathrm{~A} 2, \mathrm{D} 0, \mathrm{D} 1, \ldots, \mathrm{D} 7\} .
$$

The second major step in preparing to use genetic programming is the identification of a sufficient set of primitive functions that will be available for constructing the computer programs (S-expressions) that solve the problem. Thus, the function set $F$ for this problem is

$$
F=\{\mathrm{AND}, \mathrm{OR}, \mathrm{NOT}, \mathrm{IF}\}
$$

taking 2, 2, 1, and 3 arguments, respectively.
The IF function is the Common LISP function that performs the IF-THEN-ELSE operation. That is, the IF function returns the results of evaluating its third argument (the "else" clause) if its first argument is NIL (False) and otherwise returns the results of evaluating its second argument (the "then" clause).

The above function set $F$ is known to be sufficient to realize any Boolean function.

Since genetic programming operates on an initial population of randomly generated compositions of the available functions and terminals (and later performs genetic operations, such as crossover, on these individuals), each primitive function in the function set should be well defined for any combination of arguments from the range of values returned by every primitive function that it may encounter and the value of every terminal that it may encounter. The above function set $F$ of primitive functions satisfies the closure property.

The search space for this problem is the set of all LISP S-expressions that can be recursively composed of the primitive functions from the function set $F$ and terminals from the terminal set T. Another way to look at the search space is that the Boolean multiplexer function with $\mathrm{k}+2^{\mathrm{k}}$ arguments is a particular one of $2^{k+2^{k}}$ possible Boolean functions of $k+2^{k}$ arguments. For example, when $\mathrm{k}=3$, then $\mathrm{k}+2^{\mathrm{k}}=11$ and this
search space is of size $2^{2^{11}}$. That is, the search space is of size $2^{2048}$, which is approximately $10^{616}$.

The third major step in preparing to use genetic programming is the identification of the fitness measure for evaluating the goodness of an individual S-expression in the population. Fitness is often evaluated over a number of fitness cases - just as computer programs are typically debugged by examining their output over a number of test cases. The set of fitness cases must be representative of the problem as a whole. The reader may find it helpful to think of these fitness cases as the "environment" in which the genetic population of computer programs must adapt. There are $2^{11}=2,048$ possible combinations of the 11 arguments $\mathrm{a}_{0} \mathrm{a}_{1} \mathrm{a}_{2} \mathrm{~d}_{0} \mathrm{~d}_{1} \mathrm{~d}_{2} \mathrm{~d}_{3} \mathrm{~d}_{4} \mathrm{~d}_{5} \mathrm{~d}_{6} \mathrm{~d}_{7}$ along with the associated correct value of the 11-multiplexer function. For this particular problem, we use the entire set of 2,048 combinations of arguments as the fitness cases for evaluating fitness (although we could, of course, use sampling).

We begin by defining raw fitness in the simplest way that comes to mind using the natural terminology of the problem. The raw fitness of a LISP Sexpression in this problem is simply the number of fitness cases (taken over all 2,048 fitness cases) where the Boolean value returned by the S-expression for a given combination of arguments is the correct Boolean value. Thus, the raw fitness of an S-expression can range over 2,049 different values between 0 and 2,048. A raw fitness of 2,048 denotes a $100 \%$ correct individual S-expression.

It is useful to define a fitness measure called standardized fitness where a smaller value is better and a zero value is best. Since a bigger value of raw fitness is better for this problem, standardized fitness is different from raw fitness for this problem. In particular, standardized fitness equals the maximum possible value of raw fitness $r_{\text {max }}$ (i.e., 2,048 ) minus the observed raw fitness. The standardized fitness can also be viewed as the sum, taken over all 2,048 fitness cases, of the Hamming distances (errors) between the Boolean value returned by the S -expression for a given combination of arguments and the correct Boolean value. The Hamming distance is zero if the Boolean value returned by the S-expression agrees with the correct Boolean value and is one if it disagrees. Thus, the sum of the Hamming distances is equivalent to the number of mismatches.

The fourth major step in using genetic programming is selecting the values of certain parameters.

The two major parameters that are used to control the process are the population size $M$ and the maximum number of generations $\mathrm{N}_{\mathrm{gen}}$ to be run. $\mathrm{N}_{\text {gen }}$ was 51 throughout this article. Our choice of 4,000 as the population size for this problem reflects
an estimate on our part as to the likely complexity of this problem and the practical limitations of available computer memory.

In addition, genetic programming is controlled by a number of additional secondary parameters. Our choice of values for the various secondary parameters that control the runs of genetic programming are the same default values as we have used on numerous other problems [Koza 1992a]. Specifically, each new generation is created from the preceding generation by applying the fitness proportionate reproduction operation to $10 \%$ of the population and by applying the crossover operation to $90 \%$ of the population (with both parents selected with a probability proportionate to fitness). In selecting crossover points, $90 \%$ were internal (function) points of the tree and $10 \%$ were external (terminal) points of the tree. For the practical reason of avoiding the expenditure of large amounts of computer time on an occasional oversized programs, the depth of initial random programs was limited to 6 and the depth of programs created by crossover was limited to 17 . The individuals in the initial random generation were generated so as to obtain a wide variety of different sizes and shapes among the Sexpressions. Fitness is "adjusted" to emphasize small differences near zero. Spousal selection was also fitness proportionate. Details of the selection of these secondary parameters can be found in Koza [1992a]. We believe that sufficient information is provided herein and in Koza [1992a] to allow replication of the experimental results reported herein, within the limits inherent in a probabilistic algorithm. Common LISP software is listed in Koza [1992a] for genetic programming.

Finally, the fifth major step in preparing to use genetic programming is the selection of the criterion for terminating a run and the selection of the method for designating a result. In this problem we have a way to recognize a solution when we find it. When the raw fitness is 2,048 (i.e., the standardized fitness is zero), we have a $100 \%$ correct solution to this problem. Thus, we terminate a run after a specified maximum number of generations $\mathrm{N}_{\mathrm{gen}}$ (e.g., 51) or earlier if we find an individual with a raw fitness of 2,048 . For all the problems in this article, we will terminate a given run either after 51 generations and we designate the best single individual in the population at the time of termination as the result of genetic programming.

We now illustrate genetic programming by discussing one particular run of the Boolean 11multiplexer in detail. The process begins with the generation of the initial random population (i.e., generation 0 ).

Predictably, the initial random population includes a variety of highly unfit individuals. Many individual S-expressions in this initial random population are merely constants, such as the contradictory (AND A0
(NOT AO)). Other individuals are passive and merely pass an input through as the output, such as (NOT (NOT A1)). Other individuals are inefficient, such as (OR D7 D7). Some of these initial random individuals base their decision on precisely the wrong arguments, such as (IF DO AO A2). This individual uses the data bit DO to decide what output to take. Many of the initial random individuals are partially blind in that they do not incorporate all 11 arguments that are known to be necessary to solve the problem. Some S-expressions are just nonsense, such as

## (IF (IF (IF D2 D2 D2) D2 D2) D2 D2).

Nonetheless, even in this highly unfit initial random population, some individuals are somewhat more fit than others. For this particular run, the individuals in the initial random population had values of standardized fitness ranging from 768 mismatches (i.e., 1,280 matches) to 1,280 mismatches (i.e., 768 matches).

The worst individual in the population for the initial random generation was
(OR (NOT A1) (NOT (IF (AND A2 A0) D7 D3))).
This individual had a standardized fitness of 1,280 (i.e., raw fitness of only 768).

As it happens, a total of 23 individuals out of the 4,000 in this initial random population tied with the highest score of 1,280 matches on generation 0 . One of these 23 high scoring individuals was the S -expression
(IF A0 D1 D2).
This individual scores 1,280 matches by scoring 512 matches for the one quarter (i.e., 512) of the 2,048 fitness cases for which A2 and A1 are both NIL and by scoring an additional 768 matches on $50 \%$ of the remaining three quarters (i.e., 1,536) of the fitness cases.

This individual has obvious shortcomings. Notably, it is partially blind in that it uses only 3 of the 11 necessary terminals of the problem. As a consequence of this fact alone, this individual cannot possibly be a correct solution to the problem. This individual nonetheless does some things right. For example, this individual uses one of the three address bits (AO) as the basis for its action. It could easily have done this wrong and used one of the eight data bits. In addition, this individual uses only data bits (D1 and D2) as its output. It could have done this wrong and used address bits. Moreover, if AO (which is the low order binary bit of the 3-bit address) is T (True), this individual selects one of the three odd numbered data bits (D1) as it output. Moreover, if AO is NIL, this individual selects one of the three even numbered data bits (D2) as its output. In other words, this individual correctly links the parity of the low order address bit AO with the parity of the data bit it selects as its output. This individual is far from perfect, but it is far from being without merit. It is more fit than 3,977 of the 4,000 individuals in the population.

The average standardized fitness for all 4,000 individuals in the population for generation 0 is 985.4. This value of average standardized fitness for the initial random population forms the baseline and serves as a useful benchmark for monitoring later improvements in the average standardized fitness of the population.

The hits histogram is a useful monitoring tool based on the auxiliary hits measure. This histogram provides a way of viewing the population as a whole for a particular generation. The horizontal axis of the hits histogram is the number of hits (i.e., matches, for this problem) and the vertical axis is the number of individuals in the population scoring that number of hits. Fifty different levels of fitness are represented in the hits histogram for the population at generation 0 of this problem. In order to make this histogram legible for this problem, we have divided the horizontal axis into buckets of size 64. For example, 1,553 individuals out of 4,000 (i.e., about $39 \%$ ) had between 1,152 and 1215 matches (hits). This well-populated range includes the mode of the distribution which occurs at 1,152 matches (hits). There are 1490 individuals with 1,152 matches (hits). Figure 6 shows the hits histogram of the population for generation 0 of this run of this problem.

Figure 6 Hits histogram for generation 0.
The Darwinian reproduction operation and the genetic crossover operation are then applied to parents selected from the current population with probabilities proportionate to fitness to breed a new population. When these operations are completed, the new population (i.e., the new generation) replaces the old population.

The initial random generation is an exercise in blind random search. In going from generation 0 to generation 1, genetic programming works with the inevitable genetic variation existing in an initial random population. The search is a parallel search of the search space because there are 4,000 individual points involved.

Although the vast majority of the new offspring are again highly unfit, some of them tend to be somewhat more fit than others. Moreover, over a period of time and many generations, some of them tend to be slightly more fit than those existing in the earlier generation. In this run, the average standardized fitness of the population immediately begins improving (i.e., decreasing) from the baseline value of 985.4 for generation 0 to about 891.9 for generation 1 . We typically see this kind of generally improving trend in average standardized fitness from generation
to generation. As it happens, in this particular run of this particular problem, the average standardized fitness improves (i.e., decreases) monotonically between generation 2 and generation 9 and assumes values of $845,823,763,731,651,558,459$, and 382 , respectively. We usually see a generally improving trend in average standardized fitness from generation to generation, but not necessarily a monotonic improvement.

In addition, we similarly usually see a generally improving trend in the standardized fitness of the best single individual in the population from generation to generation. As it happens, in this particular run of this particular problem, the standardized fitness of the best single individual in the population improves (i.e., decreases) monotonically between generation 2 and generation 9. In particular, it assumes values of 640, $576,384,384,256,256,128$, and 0 (i.e., a perfect score), respectively.

On the other hand, the standardized fitness of the worst single individual in the population fluctuates considerably. For this particular run, the standardized fitness of the worst individual starts at 1280, fluctuates considerably between generations 1 and 9 , and then deteriorates (increases) to 1792 by generation 9 .

Figure 7 shows the standardized fitness (i.e., mismatches) for generations 0 through 9 of this run for the best single individual in the population, the worst single individual in the population, and the average for the population.

Figure 7 Standardized fitness of worst-of-generation individual, average standardized fitness of population, and standardized fitness of best-of-generation individual for generations 0 through 9.

In generation 1 , the raw fitness for the best single individual in the population rises to 1,408 matches (i.e., standardized fitness of 640). Only one individual in the population attained this high score of 1408 in generation 1 , namely
(IF A0 (IF A2 D7 D3) D0).
Note that this individual performs better than the best individual from generation 0 for two reasons. First, this individual considers two of the three address bits (A0 and A2) in deciding which data bit to choose as output, whereas the best individual in generation 0 considered only one of the three address bits (A0).

Second this best individual from generation 1 incorporates three of the eight data bits as its output, whereas the best individual in generation 0 incorporated only two of the eight potential data bits as output. Although still far from perfect, the best individual from generation 1 is less blind and more complex than the best individual of the previous generation. This best-of-generation individual consists of 7 points, whereas the best-of-generation individual from generation 0 consisted of only 4 points. Note that these 21 individuals are not just copies of the best-of-generation individual from generation 1. Instead, they represent a number of different programs with the same fitness, but different structure and behavior.

In generation 2, the best raw fitness remained at 1,408; however, the number of individuals in the population sharing this high score rose from 1 to 21. The high point of the hits histogram advanced from 1,152 for generation 0 to 1,280 for generation 2 . There are 1,620 individuals with 1,280 hits.

In generation 3, one individual in the population attained a new high score of 1,472 matches (i.e., standardized fitness of 576). This individual has 16 points and is
(IF A2 (IF A0 D7 D4)
(AND (IF (IF A2 (NOT D5) A0) D3 D2) D2)).
Generation 3 shows further advances in fitness for the population as a whole. The number of individuals with 1,280 hits (the high point for generation 2) has risen to 2,158 for generation 3. Moreover, the center of gravity of the fitness histogram has shifted significantly from left to right. In particular, the number of individuals with 1,280 hits or better has risen from 1,679 in generation 2 to 2,719 in generation 3.

In generations 4 and 5, the best single individual has 1,664 hits. This score is attained by only one individual in generation 4, but is attained by 13 individuals in generation 5. One of these 13 individuals is
(IF A0 (IF A2 D7 D3)
(IF A2 D4 (IF A1 D2 (IF A2 D7 D0)))).
Note that this individual uses all three address bits (A2, A1, and A0) in deciding upon the output. It also uses five of the eight data bits. By generation 4, the high point of the histogram has moved to 1,408 with 1,559 individuals.

In generation 6, four individuals attain a score of 1,792 hits. The high point of the histogram has moved to 1,536 hits.

In generation 7, 70 individuals attain this score of 1,792 hits.

In generation 8, there are four best-of-generation individuals. They all attain a score of 1,920 hits. The mode (high point) of the histogram has moved to 1,664. 1,672 individuals share this value. Moreover, an additional 887 individuals score 1,792 .

In generation 9, one individual emerges with a $100 \%$ perfect score of 2,048 hits. That individual is

## (IF A0 (IF A2 (IF A1 D7 (IF A0 D5 D0)) <br> (IF A0 (IF A1 (IF A2 D7 D3) D1) D0)) <br> (IF A2 (IF A1 D6 D4) <br> (IF A2 D4 <br> (IF A1 D2 (IF A2 D7 D0)))))

Figure 8 shows the $100 \%$ correct individual from generation 9 .

Figure 8 100\% correct individual from generation 9.
This $100 \%$ correct individual from generation 9 is a hierarchical structure consisting of 37 points (i.e., 12 functions and 25 terminals).

Note that the size and shape of this solution emerged from genetic programming. This particular size and this particular hierarchical structure was not specified in advance. Instead, it evolved as a result of reproduction, crossover, and the relentless pressure of fitness. In generation 0 , the best single individual in the population had 12 points. The number of points in the best single individual in the population varied from generation to generation. It was 4 in generation 0 , while it was 37 for generation 9 .

This $100 \%$ correct individual can be simplified to (IF A0 (IF A2 (IF A1 D7 D5) (IF A1 D3 D1))
(IF A2 (IF A1 D6 D4) (IF A1 D2 D0))).
When so rewritten, it can be seen that this individual correctly performs the 11-multiplexer function by first examining address bits A0, A2, and A1 and then choosing the appropriate one of the eight possible data bits.

Figure 9 shows, side by side, the hits histograms for generations 3, 5, 7, and 9 of this run. As one progresses from generation to generation, note the left-to-right "slinky" undulating movement of the center of mass of the histogram and the high point of the histogram. This movement reflects the improvement of the population as a whole as well as the best single individual in the population. There is a single $100 \%$ correct individual with 2,048 hits at generation 9 ; however, because of the scale of the vertical axis of this histogram, it is not visible in a population of size 4,000 .

Figure 9 Hits histograms for generations 3, 5, 7, and 9 for the 11-multiplexer.

Further insight can be gained by studying the genealogical audit trail consisting of a complete record of the details of each genetic operation that is performed at each generation. The creative role of crossover and case-splitting is illustrated by an examination of the genealogical audit trail for the $100 \%$ correct individual emerging at generation 9 .

The $100 \%$ correct individual emerging at generation 9 is the child resulting from the most common genetic operation used in the process, namely crossover. The first parent from generation 8 had rank location of 58 in the population (with a rank of 0 being the very best) and scored 1,792 hits (out of 2,048). The second parent from generation 8 had rank location 1 and scored 1,920 hits. Note that it is entirely typical that the individuals selected to participate in crossover have relatively high rank locations in the population since crossover is performed among individuals in a mating pool created proportional to fitness.

The first parent from generation 8 (scoring 1,792) was
(IF A0 (IF A2 D7 D3)
(IF A2 (IF A1 D6 D4) (IF A2 D4
(IF A1 D2 (IF A2 D7 D0)))))).
Figure 10 shows this first parent from generation 8

Figure 10 First parent (scoring 1,792 hits) from generation 8 for $100 \%$ correct individual in generation 9.

Note that this first parent starts by examining address bit $A 0$. If $A O$ is $T$, the emboldened and underlined portion then examines address bit A2. It then, partially blindly, makes the output equal D7 or D3 without even considering address bit A1. Moreover, the emboldened and underlined portion of this individual does not even contain data bits D1 and D5.

On the other hand, when $A 0$ is NIL, this first parent is $100 \%$ correct. In that event, it examines A2 and, if $A 2$ is $T$, it then examines $A 1$ and makes the output equal to D 6 or D 4 according to whether A 1 is T or NIL. Moreover, if A2 is NIL, it twice retests A2 (unnecessarily, but harmlessly) and then correctly makes the output equal to (IF A1 D2 D0). Note that the $100 \%$ correct portion of this first parent, namely, the sub-expression
(IF A2 (IF A1 D6 D4)
(IF A2 D4 (IF A1 D2 (IF A2 D7 D0))))
is itself a 6-multiplexer.
This embedded 6-multiplexer tests A2 and A1 and correctly selects amongst D6, D4, D2, and D0. This fact becomes clearer if we simplify this sub-expression by removing the two extraneous tests and removing the D7 (which is unreachable). This sub-expression simplifies to the following:
(IF A2 (IF A1 D6 D4)
(IF A1 D2 D0))
In other words, this imperfect first parent handles part of its environment correctly and part of its environment incorrectly. In particular, this first parent handles the even-numbered data bits correctly and is partially correct in handling the odd-numbered data bits.

The tree representing this first parent has 22 points. The crossover point chosen at random at the end of generation 8 was point 3 and corresponds to the second occurrence of the function IF. That is, the crossover fragment consists of the incorrect, emboldened and underlined sub-expression

## (IF A2 D7 D3).

The second parent from generation 8 (scoring 1,920 hits) was
(IF A0 (IF A0
(IF A2 (IF A1 D7 (IF A0 D5 D0))
(IF A0 (IF A1 (IF A2 D7
D3)
D1)
D0))
(IF A1 D6 D4))
(IF A2 D4
(IF A1 D2
(IF A0 D7 (IF A2 D4 D0))))))
Figure 11 shows the second parent from generation 8.

Figure 11 Second parent (scoring 1,920 hits) from generation 8 for $100 \%$ correct individual in generation 9.

The tree representing this second parent has 40 points. The crossover point chosen at random for this second parent was point 5 . This point corresponds to the third occurrence of the function IF. That is, the crossover fragment consists of the emboldened and underlined sub-expression of this second parent.

This sub-expression of this second parent $100 \%$ correctly handles the case when $A 0$ is $T$ (i.e., the odd numbered addresses). This sub-expression makes the output equal to $D 7$ when the address bits are 111 ; it makes the output equal to D5 when the address bits are 101; it makes the output equal to D3 when the address bits are 011 ; and it makes the output equal to D1 when the address bits are 001 .

Note that the $100 \%$ correct portion of this second parent, namely, the sub-expression
(IF A2 (IF A1 D7 (IF A0 D5 D0))
(IF A0 (IF A1 (IF A2 D7 D3) D1) D0))
is itself a 6-multiplexer.
This embedded 6-multiplexer in this second parent tests A2 and A1 and correctly selects amongst D7, D5, D3, and D1 (i.e., the odd numbered data bits). This fact becomes clearer if we simplify this sub-expression of this second parent to the following:
(IF A2 (IF A1 D7 D5)
(IF A1 D3 D1)
In other words, this imperfect second parent handles part of its environment correctly and part of its environment incorrectly. This second parent does not do very well when AO is NIL (i.e., the even numbered data bits). This second parent correctly handles the
odd-numbered data bits and incorrectly handles the even-numbered data bits.

Even though neither parent is perfect, these two imperfect parents contain complementary portions which, when mated together, produce a $100 \%$ correct offspring individual. In effect, the creative effect of the crossover operation blends the two cases of the implicitly "case-split" environment into a single $100 \%$ correct solution.

Figure 12 shows this case splitting by showing the $100 \%$ correct offspring from generation 9 as two 6multiplexers:

Figure 12 Simplified $100 \%$ correct individual from generation 9 shown as a hierarchy of two 6 multiplexers.

Figure 13 also shows this simplified version of the $100 \%$ correct individual from generation 9 .

Figure 13 Simplified $100 \%$ correct individual from generation 9 shown as a hierarchy of two 6 multiplexers.

Of course, not all crossovers between individuals are useful and productive. In fact, a large fraction of the individuals produced by the genetic operations are useless. But the existence of a population of alternative solutions to a problem provides the ingredients with which genetic recombination (crossover) can produce some improved individuals. The relentless pressure of natural selection based on fitness then causes these improved individuals to be preserved and to proliferate. Moreover, genetic variation and the existence of a population of alternative solutions to a problem makes it unlikely that the entire population will become trapped on local maxima.

Interestingly, the same crossover that produced the $100 \%$ correct individual also produced a runt scoring only 256 hits. In this particular crossover, the two crossover fragments not used in the $100 \%$ correct individual combined to produce an unusually unfit individual. This is one of the reasons why there is
considerable variability from generation to generation in the worst single individual in the population.

As one traces the ancestry of the $100 \%$ correct individual created in generation 9 deeper back into the genealogical audit tree (i.e., towards earlier generations), one encounters parents scoring generally fewer and fewer hits. That is, one encounters more Sexpressions that perform irrelevant, counterproductive, partially blind, and incorrect work. But if we look at the sequence of hits in the forward direction, we see localized hill-climbing in the search space occurring in parallel throughout the population as the creative operation of crossover recombines complementary, coadapted portions of parents to produce improved offspring.

The solution to the 11-multiplexer problem in this run was a hierarchy consisting of two 6-multiplexers. In a run where we applied genetic programming to the simpler Boolean 6-multiplexer, we obtained the following $100 \%$ correct solution
(IF (AND A0 A1) D3 (IF A0 D1 (IF A1 D2 D0))).
This solution to the 6 -multiplexer is also a hierarchy. It is a hierarchy that correctly handles the particular fitness cases where (AND A0 A1) is true and then correctly handles the remaining cases where (AND A0 A1) is false.

Default hierarchies often emerge from genetic programming. A default hierarchy incorporates partially correct sub-rules into a perfect overall procedure by allowing the partially correct (default) sub-rules to handle the majority of the environment and by then dealing in a different way with certain specific exceptional cases in the environment. The Sexpression above is also a default hierarchy in which the output defaults to
(IF A0 D1 (IF Al D2 D0))
three quarters of the time. However, in the specific exceptional fitness case where both address bits (A0 and A 1 ) are both T , the output is the data bit D3.

Default hierarchies are considered desirable in induction problems [Holland 1986, Holland et. al. 1986, Wilson 1988] because they are often parsimonious and they are a human-like way of dealing with situations.

## 5. Symbolic Regression - Empirical Data

An important problem area in virtually every area of science is finding the relationship underlying empirically observed values of the variables measuring a system. In practice, the observed data may be noisy and there may be no known way to express the relationships involved in a precise way.

The learning of the Boolean multiplexer function is an example of the general problem of symbolic function identification (symbolic regression). In this
section, we discuss symbolic regression as applied to real-valued functions over real-valued domains.

In conventional linear regression, one is given a set of values of various independent variable(s) and the corresponding values for the dependent variable(s). The goal is to discover a set of numerical coefficients for a linear combination of the independent variable(s) which minimizes some measure of error (such as the square root of the sum of the squares of the differences) between the given values and computed values of the dependent variable(s). Similarly, in quadratic regression, the goal is to discover a set of numerical coefficients for a quadratic expression which similarly minimizes error.

Of course, it is left to the researcher to decide whether to do a linear regression, quadratic regression, a higher order polynomial regression, or whether to try to fit the data points to some non-polynomial family of functions (e.g., sines and cosines of various periodicities, etc.). But, often, the issue is deciding what type of function most appropriately fits the data, not merely computing the numerical coefficients after the type of function for the model has already been chosen. In other words, the real problem is often both the discovery of the correct functional form that fits the data and the discovery of the appropriate numeric coefficients that go with that functional form. We call the problem of finding a function, in symbolic form, that fits a given finite sample of data by the name "symbolic regression." It is "data to function" regression.

The problem of discovering empirical relationships from actual observed data is illustrated by the wellknown non-linear econometric exchange equation

$$
\mathrm{P}=\frac{\mathrm{MV}}{\mathrm{Q}} .
$$

This equation states the relationship between the gross national product Q of an economy, the price level P , the money supply M, and the velocity of money V.

Suppose that our goal is to find the econometric model expressing the relationship between quarterly values of the price level P and the quarterly values of the three other quantities appearing in the equation. That is, our goal is to rediscover the relationship

$$
\mathrm{P}=\frac{\mathrm{MV}}{\mathrm{Q}}
$$

from the actual observed noisy time series data. Moreover, suppose that certain additional economic data is also available which is irrelevant to this relationship, but not preidentified as being irrelevant. Many economists believe that inflation (which is the change in the price level) can be controlled by the central bank via adjustments in the money supply M. Specifically, the "correct" exchange equation for the United States in the postwar period is the non-linear relationship

$$
\mathrm{GD}=\frac{(1.6527 * \mathrm{M} 2)}{\mathrm{GNP} 82}
$$

where 1.6527 is the actual long-term historic postwar value of the M2 velocity of money in the United States [Hallman et. al. 1989]. Interest rates are not a relevant variable in this well-known relationship.

In particular, suppose we are given the 120 actual quarterly values from 1959:1 (i.e., the first quarter of 1959) to $1988: 4$ of following four econometric time series:

- Inflation or price level $P$ (the dependent variable here) is represented by the Gross National Product Deflator (normalized to 1.0) for 1982 (conventionally called GD).
- The gross national product of the economy Q (one of the independent variables) is represented by the annual rate for the United States Gross National Product in billions of 1982 dollars (conventionally called GNP82).
- The money supply $M$ (another of the independent variables) is represented by the monthly values of the seasonally adjusted money stock M2 in billions of dollars, averaged for each quarter (conventionally called M2).
- Interest rates (an independent variable that happens to be irrelevant to the calculation here) are represented by the monthly interest rate yields of 3month Treasury bills, averaged for each quarter (conventionally called FYGM3).
The four time series used here were obtained from the CITIBASE data base of machine-readable econometric time series [Citibank 1989].

As a point of reference, the sum of the squared errors between the actual gross national product deflator GD from 1959:1 to 1988:4 and the fitted GD series calculated from the above model over the entire 30 -year period involving 120 quarters (1959:1 to 1988:4) is very small, namely 0.077193 . The correlation $\mathrm{R}^{2}$ was 0.993320 .

These 120 combinations of the above three independent variables (M2), and the associated value of the dependent variables (GD, GNP82, and FYGM3) are the set from which we will draw the fitness cases that will be used to evaluate the fitness of any proposed S-expression.

The goal is to find a function, in symbolic form, that is a good fit or perfect fit to the numerical data points. The solution to this problem of finding a function in symbolic form that fits a given sample of data can be viewed as a search for a mathematical expression (S-expression) from a space of possible Sexpressions that can be composed from a set of available functions and arguments.

The appearance of numeric constants (such as the constant 1.6527 in the above correct equation) is typical of relations among empirical data from the real world. Thus, we must deal with the problem of discovering coefficients and constant values while doing symbolic regression.

Constants can be created in genetic programming by adding an ephemeral random constant $\leftarrow$ to the terminal set. During the creation of generation 0 , whenever the ephemeral random constant $\leftarrow$ is chosen for an endpoint of the tree, a random number of an appropriate type in a specified range is generated and attached to the tree at that point. For example, in the real-valued symbolic regression problem at hand, the ephemeral random constants are of floating point type and their range is between -1.000 and +1.000 .

This random generation is done anew each time when an ephemeral $\leftarrow$ terminal is encountered, so that the initial random population contains a variety of different random constants of the specified type. Once generated and inserted into the S-expressions of the initial random population, these constants remain fixed thereafter. However, after the initial random generation, the numerous different random constants will be moved around from tree to tree by the crossover operation. In many instances, these constants will be combined via the arithmetic operations in the function set of the problem.

This "moving around" and "combining" of the random constants is not at all haphazard, but, instead, is driven by the overall goal of achieving ever better levels of fitness. For example, a symbolic expression that is a reasonably good fit to a target function may become a better fit if a particular constant is, for example, decreased slightly. A slight decrease can be achieved in several different ways. For example, there may be a multiplication by 0.90 , a division by 1.10 , a subtraction of 0.08 , or an addition of -0.004 . If a decrease of precisely 0.09 in a particular constant would produce a perfect fit, a decrease of 0.07 will usually fit better than a decrease of only 0.05 . Thus, the relentless pressure of the fitness function in the natural selection process determines both the direction and magnitude of the adjustments of the original numerical constants. It is thus possible to genetically evolve numeric constants as required to perform a required symbolic regression on numeric data.

We first divide the 30 -year, 120 -quarter period into a 20 -year, 80 -quarter in-sample period running from 1959:1 to $1978: 4$ and a 10 -year, 40-quarter out-ofsample period running from 1979:1 to 1988:4. This allows us to use the first two-thirds of the data to create the model and to then use the last third of the data to test the model.

The first major step in using genetic programming is to identify the set of terminals. The terminal set for this problem is

$$
\mathrm{T}=\{\mathrm{GNP} 82, \mathrm{FM} 2, \text { FYGM3 }, \leftarrow\} .
$$

The terminals GNP82, FM2, and FYGM3 correspond to the independent variables of the model and provide access to the values of the time series. In effect, these terminals are functions of the unstated, implicit time variable which ranges over the various quarters.

The second major step in using genetic programming is to identify a set of functions. The set of functions chosen for this problem is

$$
\mathrm{F}=\quad\{+,-, *, \%, \mathrm{EXP}, \mathrm{RLOG}\}
$$

taking $2,2,2,2,1$, and 1 arguments, respectively.
It is necessary to ensure closure by protecting against the possibility of division by zero and the possibility of creating extremely large or small floating point values. Accordingly, the protected division function \% ordinarily returns the quotient; however, if division by zero is attempted, it returns 1.0 . The oneargument exponential function EXP ordinarily returns the result of raising $e$ to the power indicated by its one argument. If the result of evaluating EXP or any of the four arithmetic functions would be greater than $10^{10}$ or less than $10^{-10}$, then the nominal value $10^{10}$ or $10^{-}$ 10 , respectively, is returned. The protected logarithm function RLOG returns 0 for an argument of 0 and otherwise returns the logarithm of the absolute value of the argument.

Notice that we are not told a priori whether the unknown functional relationship between the given observed data (the three independent variables) and the target function (the dependent variable, GD) is linear, polynomial, exponential, logarithmic, nonlinear, or otherwise. The unknown functional relationship could be any combination of the functions in the function set. Notice also that we are also not given the known constant value V for the velocity of money. And, notice that we are not told that the 3month Treasury bill yields (FYGM3) contained in the terminal set and the addition, subtraction, exponential, and logarithm functions are all irrelevant to finding the econometric model for the dependent variable GD of this problem.

The third major step in using genetic programming is identification of the fitness function for evaluating how good a given computer program is at solving the problem at hand.

The fitness of an S-expression is the sum, taken over the 80 in-sample quarters, of squares of differences between the value of the price level produced by S-expression and the target value of the price level given by the GD time series.

Population size was 500 here.
The initial random population (generation 0) was, predictably, highly unfit. In one run, the sum of squared errors between the single best S-expression in the population and the actual GD time series was 1.55 . The correlation $\mathrm{R}^{2}$ was 0.49 .

As before, after the initial random population was created, each successive new generation in the population was created by applying the operations of fitness proportionate reproduction and genetic recombination (crossover).

In generation 1 , the sum of the squared errors for the new best single individual in the population improved to 0.50 .

In generation 3, the sum of the squared errors for the new best single individual in the population improved to 0.05 . This is approximately a 31 -to- 1 improvement over the initial random generation. The value of $\mathrm{R}^{2}$ improved to 0.98 . In addition, by generation 3, the best single individual in the population came within $1 \%$ of the actual GD time series for 44 of the 80 in -sample points.

In generation 6, the sum of the squared errors for the new best single individual in the population improved to 0.027 . This is approximately a 2 -to- 1 improvement over generation 3 . The value of $\mathrm{R}^{2}$ improved to 0.99 .

In generation 7, the sum of the squared errors for the new best single individual in the population improved to 0.013 . This is approximately a 2 -to- 1 improvement over generation 6 .

In generation 15 , the sum of the squared errors for the new best single individual in the population improved to 0.011 . This is an additional improvement over generation 7 and represents approximately a 141-to- 1 improvement over generation 0 . The correlation $\mathrm{R}^{2}$ was 0.99 .

In one run, the best single individual had a sum of squared errors of only 0.009272 over the in-sample period. Figure 14 graphically depicts this best-of-run individual.

Figure 14 Best-of-run individual for exchange equation problem.

This best-of-run individual is equivalent to

$$
\mathrm{GD}=\frac{(1.634 * \mathrm{M} 2)}{\mathrm{GNP} 82}
$$

Notice the sub-tree (* $-0.4020-0.583$ ) on the left of this best-of-run individual. This sub-expression evaluates to +0.234 . The numeric constants -0.4020 and -0.583 were created in generation 0 by the constant creation process. These two constants are combined into a new constant ( +0.234 ), which, in conjunction with other such constants, eventually produces the overall 1.634 constant as the velocity of money.

Although genetic programming has succeeded in finding an expression that fits the given data rather well, there is always a concern that a fitting technique may be overfitting (i.e., memorizing) the data. If a fitting technique overfits the data, the model produced has no ability to generalize to new combinations of the independent variables and therefore has little or no predictive or explanatory value. We can validate the model produced from the 80 -quarter in-sample period with the data from the 40 -quarter out-of-sample period.

Table 1 shows the sum of the squared errors and $\mathrm{R}^{2}$ for the entire 120 -quarter period, the 80 -quarter insample period, and the 40 -quarter out-of-sample period.

Table 1 Comparison of in-sample and out-ofsample periods

| Data Range | $1-120$ | $1-80$ | $81-120$ |
| :--- | :--- | :--- | :--- |
| $\mathrm{R}^{2}$ | 0.993480 | 0.997949 | 0.990614 |

Figure 15 shows both the gross national product deflator GD from 1959:1 to 1988:4 and the fitted GD series calculated from the above genetically produced model for 1959:1 to 1988:4. The actual GD series is shown as a line with dotted points. The fitted GD series calculated from the above model is an ordinary line.

Figure 15 Gross national product deflator and fitted series computed from genetically produced model.

Figure 16 shows the residuals from the fitted GD series calculated from the above genetically produced model for 1959:1 to 1988:4.

Figure 16 Residuals between the gross national product deflator and fitted series computed from genetically produced model

We can further increase confidence that this genetically evolved model is not overfitting the data by dividing the same 30 -year period into a different set of in-sample and out-of-sample periods. When we divide the 30 -year, 120 -quarter period into a 10 -year, 40-quarter out-of-sample period running from 1959:1 to $1968: 4$ and a 20 -year, 80 -quarter in-sample period running from 1969:1 to 1988:4, we obtain a virtually identical model. See Koza [1992a].

## 6. Control - Truck Backer-Upper

Problems of optimal control involve a system that is described by state variables. The future state of the system is determined by the choice of certain control variables. The objective in optimal control is to
choose the control variables so as to cause the system to go to a specified target state with an optimal (typically minimal) cost.

Anyone who has tried to back up a tractor-trailer truck to a loading dock knows that it presents a difficult problem of control. Nguyen and Widrow [1990] successfully illustrated the capabilities of neural networks by finding a controller for this multidimensional control problem.

Problems of control can be viewed as requiring the discovery of a computer program (i.e. controller, control strategy) that takes the state variables of a problem as its inputs and produces the values of the control variable(s) as its outputs.

Genetic programming is well suited to difficult control problems where no exact solution is known and where an exact solution is not required. When genetic programming solves a problem, it produces a computer program that takes the state variables of the system as input and produces the actions required to solve the problem as output. The solution to a problem produced by genetic programming is not just a numerical solution applicable to a single specific numerical combination of states, but, instead, comes in the form of a general function (computer program) that maps the state variables of the system into values of the control variable(s). There is no need to specify the exact size and shape of the computer program in advance. The needed structure is evolved in response to the selective pressures of Darwinian natural selection and genetic sexual recombination.

The truck backer-upper problem is a four dimensional control problem. Figure 17 shows a loading dock and tractor-trailer. The loading dock is the Y -axis. The trailer and tractor are connected at a pivot point.

The state space of the system is four dimensional. X is the horizontal position of the midpoint of the rear of the trailer and Y is the vertical position of the midpoint. The target point for the midpoint of the rear of the trailer is $(0,0)$. The angle $\theta t$ (also called TANG) is the angle of the trailer with respect to the loading dock (measured, in radians, from the positive X -axis with counterclockwise being positive). The difference angle $\theta_{d}$ (also called DIFF) is the angle of the tractor relative to the longitudinal axis of the trailer (measured, in radians, from the longitudinal axis of the trailer with counterclockwise being positive).

Figure 17 In the truck backer-upper problem, the goal is to bring the midpoint of the rear of the trailer to the target point $(0,0)$ on the loading dock. The control variable is the steering angle $u(t)$ for the tires of the tractor (cab). The cab is connected to the trailer via the pivot.

The truck backs up at a constant speed so that the front wheels of the tractor (cab) move a fixed distance backwards with each time step. Steering is accomplished by changing the angle $u$ (i.e. the control variable) of the front tires of the tractor (cab) with respect to the current orientation of the tractor.

The goal is to guide the midpoint of the rear of the trailer so that it ends up at (or very close to) the target point $(0,0)$ on the loading dock while never allowing the midpoint of the rear of the truck to touch the loading dock. We want to find a control strategy which specifies the change in angle $u$ of the front tires of the tractor (cab) in terms of the four state variables of the system (namely, X, Y, TANG, and DIFF)

The equations of motion that govern the tractortrailer system are

$$
\begin{aligned}
& A=\mathrm{r} \cos u[\mathrm{t}] \\
& B=A \cos \left(\theta_{\mathrm{c}}[t]-\theta t[t]\right) \\
& C=A \sin \left(\theta_{C}[\mathrm{t}]-\theta t[\mathrm{t}]\right) \\
& \mathrm{x}[t+1]=\mathrm{x}[t]-B \cos \theta t \\
& \mathrm{y}[t+1]= \\
& \mathrm{y}[t]-B \sin \theta t \\
& \theta_{\mathrm{c}}[t+1]= \\
&\left.\tan ^{-1} \text { Error! }\right) \\
& \theta t[t+1]=\tan ^{-1} \text { Error!) } \\
& \theta_{d}[t]=\theta_{t}[t]-\theta_{c}[t]
\end{aligned}
$$

In these equations, $\tan ^{-1}\left(\frac{x}{y}\right)$ is the two argument arctangent function (also called ATG here) delivering an angle in the range $-\pi$ to $\pi$. The length of the tractor (i.e. cab) $d_{\mathrm{C}}$ is 6 meters and the length of the trailer $d_{\mathrm{S}}$ is 14 meters. As in Nguyen and Widrow [1990], the truck only moves backwards. The distance moved in one time step is $r$. The angle $\theta_{t}$ is TANG. The angle of the tractor relative to the X axis is $\theta_{\mathrm{c}}$.

The first major step in preparing to use genetic programming is to identify the set of terminals. The four state variables of the system (i.e. X, Y, TANG, DIFF) can be viewed as inputs to the unknown computer program which we want to find for controlling the system. Thus, the terminal set T for this problem is $\mathrm{T}=\{\mathrm{X}, \mathrm{Y}$, TANG, DIFF, $\leftarrow\}$. When the initial population of random individuals is created, every occurrence of this ephemeral random constant in an S-expression is replaced by a separately generated random floating point number in the range between 1.000 and +1.000 .

The second major step in preparing to use genetic programming is to identify a sufficient set of functions to solve for the problem. We do not know the solution to this problem. We have no assurance that a chosen function set will be sufficient for the problem. However, the function set F consisting of four arithmetic operations, the two argument Arctangent function ATG, and the conditional comparative operator IFLTZ ("If Less than Zero") seems reasonable. Thus, the function set for this problem is $\mathrm{F}=\{+,-, *, \%$, ATG, IFLTZ $\}$. taking 2, 2, 2, 2, 2, and

3 arguments, respectively. The protected division function \% returns one when division by zero is attempted, and, otherwise, returns the normal quotient. The conditional branching operator IFLTZ ("If Less than Zero") evaluates its third argument is its first argument is less than zero and otherwise evaluates its second argument. Since IFLTZ returns a floating point value and $\%$ protects against division by zero, there is closure among the functions of the function set. The IFLTZ operator is implemented as a macro [Koza 1992a].

In selecting this function set, we included the Arctangent function ATG because we thought it might be useful in computing angles from the various distances involved in this problem and we included the conditional comparative operator IFLTZ so that actions could be made conditional on certain conditions being satisfied. As it developed, ATG did not appear in the best solution we found. It is, of course, necessary to choose a function set and terminal set that together are capable and sufficient to solve the problem at hand. We had no assurance, in advance, that this function set and terminal set would be sufficient to solve this problem.

The third major step in preparing to use genetic programming is the identification of the fitness measure for evaluating how good a given computer program is at solving the problem at hand. For this problem, fitness is an error measure. Each program is tested against a simulated environment consisting of eight fitness cases, each consisting of a set of initial conditions for $\mathrm{X}, \mathrm{Y}$, and TANG. X is either 20 or 40 meters. Y is either -50 or 50 meters. TANG is either $\pi / 2$ or $+\pi / 2$. As in Nguyen and Widrow [1990], the difference angle DIFF is initially always zero (i.e. the tractor and trailer are initially coaxial).

Time is measured in time steps of 0.02 seconds. A total of 3000 time steps (i.e. 60 seconds) are allowed for each fitness case The speed of the tractor-trailer is 0.2 meters per time step. Termination of a fitness case occurs when (1) time runs out, (2) the trailer crashes into the loading dock (i.e. X becomes zero), or (3) the midpoint of the rear of the trailer comes close to the target $(0,0)$ point. A hit for this problem occurs when the value of X is less than 0.1 meters, the absolute value of $Y$ is less than 0.42 meters, and the absolute value of TANG is less than 0.12 radians (i.e. about 14 degrees).

Fitness is the sum, over the fitness cases, of the sum of the squares of the differences, at the time of termination of the fitness case, between the value of X and the target value of $X$ (i.e. 0 ), the difference between the value of $Y$ and the target value of $Y$ (i.e. 0 ), and difference between the value of TANG and the target value of TANG (i.e. 0).

A wrapper (output interface) is used to convert the value returned by a given individual computer program to a value appropriate to the problem domain.

In particular, if the program evaluates to a number between -1.0 and +1.0 , the tractor turns its wheels to that particular angle (in radians) relative to the longitudinal axis of the tractor and backs up for one time step at a constant speed. Outside that range the control variable saturates.

As in Nguyen and Widrow [1990], if a choice of the control variable $u$ would cause the absolute value of difference DIFF to exceed 90 degrees, DIFF is constrained to 90 degrees to prevent jack-knifing.

The population size is 1,000 here.
We will terminate a given run of this problem when either (i) genetic programming produces a computer program for which all eight fitness cases terminate according to condition (3) above, or (ii) 51 generations have been run.

In one run, the best single individual computer program in the initial population of randomly created individual programs was, as one would expect, incapable of backing the tractor-trailer to the loading dock for any of the eight initial conditions (fitness cases) of the tractor-trailer truck. This best-ofgeneration individual program had an enormous value of fitness, namely 26,956 . This S-expression has 19 points and is shown below:
(- (ATG (+ X Y) (ATG X Y)) (IFLTZ (- TANG X) (IFLTZ Y TANG TANG) (* 0.3905 DIFF)))

However, even in generation 0 , some individuals are better than others.

In the next few generations, fitness began to improve (i.e. drop) substantially. It dropped to 4790 for generations 1 and 2, 3131 in generation 3, and 228 for generations 4 and 5. Moreover, in addition to coming closer to the loading dock, for generations 4 and 5, the best-of-generation individual was successful in backing up the truck for one of the eight fitness cases.

Fitness improved to 202 for generation 6. By generation 11, fitness had improved to 38.9 and the best-of-generation individual was successful for three of the eight fitness cases. Between generations 14 and 21, fitness for the best-of-generation individual ranged between 9.99 and 9.08 and the best-of-generation individual was successful for five fitness cases. Between generation 22 and 25, fitness for the best-ofgeneration individual ranged between 8.52 and 8.47 and the best-of-generation individual was successful for seven fitness cases. Of course, the vast majority of individual computer programs in the population were still ineffective in solving the problem (although average performance is also improving).

In generation 26, the fitness of the best-ofgeneration individual had improved to 7.41. This best-of-generation control strategy was capable of backing up the tractor-trailer to the loading dock for all eight fitness cases. This computer program has 108 points (i.e. functions and terminals) and is shown below.

$(\% \mathrm{Y}$ TANG $))(-$ DIFF X) $)(+(-0.0728 \mathrm{Y})(\% \mathrm{Y}$ TANG $))$ )
(- DIFF X)) (+ (- -0.0728 Y) (IFLTZ DIFF Y (\% Y TANG) )) (\% Y TANG)) TANG) (- (\% (\% (+ (+ (IFLTZ Y Y (\% Y TANG) ) (- TANG X) ) (+ (- -0.0728 Y) (\% Y
TANG))) TANG) TANG) X) ) ( (- DIFF X)) $(+(+(+(+(+$
(IFLTZ DIFF Y (\% Y TANG)) (- DIFF X)) (+ (--0.0728
Y) (\% Y TANG)) (- DIFF X)) (+ (- -0.0728 Y) (\% Y TANG)) (\% Y TANG))) TANG)

As can be seen, this simplified function partitions the space into two parts according to the sign of $Y$.

Note that this S-expression is probably not a timeoptimal solution, since it uses two different strategies for handling two cases that could, in fact, be handled in a symmetric way. Nonetheless, the S-expression does the job and scores maximal fitness with the distance-based fitness measure being used for this problem (which does not specifically call for time optimality).

Figure 18 shows the curved trajectory of the midpoint of the back of the trailer for one of the four fitness cases for which $Y$ is negative for the best-of-run individual from generation 26.

Figure 18 Curved trajectory of the back of trailer for a fitness cases for which $Y$ is negative for the best-of-run individual of the truck backer upper problem.

Figure 19 shows the almost linear trajectory of the midpoint of the back of the trailer for one of the four fitness cases for which $Y$ is positive for the best-of-run individual from generation 26.

Figure 19 Almost linear trajectory of the back of trailer for a fitness cases for which $Y$ is positive for the best-of-run individual of the truck backer upper problem.

No mathematically exact solution to this problem is known. The above control strategy is almost certainly not the exact solution. However, this genetically created control strategy works. It is an approximately correct computer program that emerged from a competitive genetic process that searches the space of possible programs for a satisficing result.

Interestingly, on $89.6 \%$ of the time steps involved in evaluating the above best-of-generation individual from generation 26, the absolute value of the control variable returned by this individual exceeded one (i.e., the genetically evolved solution chose to apply a bangbang force).

Note also that we did not pre-specify the size and shape of the solution. We did not specify that the solution would have 108 points. As we proceeded from generation to generation, the size and shape of the best-of-generation individuals changed as a result of the selective pressure exerted by the fitness measure and the genetic operations. For example, there were only 19 points for the best-of-generation individual for generation 0 (i.e. the initial random generation).

Note that the 108 point computer program from generation 26 could easily be encoded into a controller using ones preferred programming language.

On this particular run, we obtained a control strategy satisfying the termination criterion of the problem after processing 27,000 individuals (i.e. 1,000 individuals for an initial random generation and 26 additional generations). We have achieved similar results in other runs of this problem.

The difficulty of this problem arises, of course, from Nguyen and Widrow's choice of the four states [Geva, Sitte, and Willshire, 1992].

Koza and Keane [1990a, 1990b] have applied genetic programming to the cart centering and broom balancing problems.

## 7. Classification - Intertwined Spirals

Learning problems often present themselves as problems of classification. In classification problems, the goal is to discern a pattern and to develop a procedure capable of successfully performing the classification. The procedure is typically developed using a sample of data and is considered successful if it learns to correctly classify both the original sample and previously unseen points that are a reasonable generalization of the original sample points. Learning relationships that successfully discriminate among instances associated with problem solving choices is one approach to problem solving in artificial intelligence.

Lang and Whitbrock [1989] used a neural network to solve the challenging problem of distinguishing two intertwined spirals. In their statement of the problem, the two spirals coil around the origin three times in the $x-y$-plane. The $x-y$-coordinates of 97 points from each spiral are given. The problem involves learning to classify each point as to which spiral it belongs.

Figures 20 and 21 show the two spirals. The 97 points of the first spiral are indicated by large or small squares and the 97 points of the second spiral are indicated by large or small circles. The first spiral belongs to class +1 and the second spiral belongs to class -1 . The task as defined by Lang and Whitbrock is limited to the 194 points in the three turns of these two spirals and does not involve dealing with points that would lie on a fourth or later turns of the extensions of the same spirals. The difficulty of this problem arises, of course, from Lang and Whitbrock's choice of Cartesian coordinates (as opposed to, say, polar coordinates).

The terminal set for this problem consists of the x and y position of the 194 given points. In addition, since we may need numerical constants in a computer program capable of processing the 194 given points, we include the ephemeral random floating point constant $\leftarrow$ in the terminal set. Thus, the terminal set is $T=\{X, Y, \leftarrow\}$.

As to the function set for this problem, it seems reasonable to try to write a computer program for determining to which spiral a given point belongs in terms of the four arithmetic operations, a conditional comparative function for decision making, and the trigonometric sine and cosine functions. Thus, the function set for this problem is $\mathrm{F}=(+,-, *, \%$, IFLTE, SIN, COS $\}$, taking 2, 2, 2, 2, 4, 1, and 1 arguments, respectively.

IFLTE (If-Less-Than-or-Equal) is a four-argument conditional comparative operator that executes its third argument if its first argument is less than its second argument and, otherwise, executes the fourth (else)
argument. The IFLTE operator is implemented as a macro [Koza 1992a].

Since the S-expressions in the population are compositions of functions and terminals operating on floating point numbers and since the S -expressions in this problem must produce a binary output ( +1 or -1 ) to designate the class, a wrapper (output interface) is required. This wrapper maps any positive value to class +1 and maps any other value to class -1 .

The fitness of an individual S -expression is computed using fitness cases. The fitness cases are the $194 x$-y coordinates of the given points belonging to the spirals and the class $(+1$ or -1$)$ associated with each point. Raw fitness (hits) is the number of points ( 0 to 194) that are correctly classified.

The population size is 10,000 here. We will terminate a given run when either (i) genetic programming produces a computer program which scores a raw fitness of 194, or (ii) 51 generations have been run.

As one would expect, the individual S-expressions in the initial population of randomly created computer programs are highly unfit in solving the problem. In one run, approximately $31 \%$ of the initial random individuals in generation 0 correctly classified precisely $50 \%$ of the points (i.e., 97 out of a possible 194 points). Some of these individuals, such as (* (* X X) 0.502), scored $50 \%$ by virtue of always returning a value with the same sign and therefore classifying all the points as belonging to one spiral. Others, such as (* X Y) scored $50 \%$ by virtue of dividing the space into parts which contain exactly half of the points. In addition, about $30 \%$ of the population scored between 88 and 96 hits while about $32 \%$ scored between 98 and 106 hits. The worst-of-generation individual from generation 0 scored 71 hits while the best-ofgeneration individual scored 128 hits.

The best-of-generation individual from generation 0 scored 128 hits out of a possible 194 hits and is below:
(SIN (\% Y 0.30400002))
In generation 1, a partially blind best-of-generation individual works by classifying points into vertical bands of varying width. Because it is particularly effective near the X -axis, it does better than the best-of-generation individual from generation 0 .

## Insert Fig. 20 here

Figure 20 Classification performed by best-ofgeneration individual from generation 3.

For generation 3, the best-of-generation individual contained 48 points, scored 139 hits, and incorporated both X and Y . It is shown below:
(SIN (- (+ (IFLTE (* X -0.25699997) (* X X) (COS Y) (+ (SIN (COS X)) $\left(+{ }^{*} 0.18500006-0.33599997\right)$ (IFLTE Y 0.42000008 X -0.23399997)) )) (SIN (SIN Y))) (+ (IFLTE
$(\%(\operatorname{COS~X})($ SIN -0.594$))(+-0.553 \mathrm{Y})(\% \mathrm{Y}-0.30499995)$ (+ Y X)) (COS (\% X 0.5230001)))))

Figure 20 shows that the best-of-generation individual from generation 3 does especially well near the origin. The points of one spiral are indicated with boxes and the points of the other spiral are indicated with circles. Correctly classified points are indicated by large boxes or circles.

## Insert Fig. 20 here

Figure 21 Classification performed by best-ofgeneration individual from generation 33.

On generation 33, the best-of-generation individual scored 192 out of 194 . It had 169 points. Figure 21 shows the classification performed by the best-ofgeneration individual scoring 192 from generation 33. There are now only two incorrectly classified points in this figure. One is shown as a small circle in a region in the upper left section of the figure which the Sexpression incorrectly classified as gray, instead of white. The second is shown as a small square in the lower right section of the figure which the $S$ expression incorrectly classified as white, instead of gray.

On generation 36, the following S-expression containing 179 points and scoring 194 out of 194 hits emerged:
(SIN (IFLTE (IFLTE $(+\mathrm{Y} Y)(+\mathrm{X} \mathrm{Y})(-\mathrm{X} \mathrm{Y})(+\mathrm{Y} Y))$ (* $^{*}$ X X) (SIN (IFLTE (\% Y Y) (\% (SIN (SIN (\% Y $0.30400002)$ ) ) X) (\% Y 0.30400002 ) (IFLTE (IFLTE (\% (SIN (\% (\% Y (+X Y) 0.30400002$))(+\mathrm{X} \mathrm{Y}))(\% \mathrm{X}$ -$0.10399997)(-\mathrm{X} \mathrm{Y}))^{*}(+-0.12499994-0.15999997)(-\mathrm{X}$ Y))) 0.30400002 (SIN (SIN (IFLTE (\% (SIN (\% (\% Y 0.30400002 ) 0.30400002) ) (+ X Y)) (\% (SIN Y) Y) (SIN (SIN (SIN (\% (SIN X) (+ -0.12499994-0.15999997)))) ) (\% (+ (+ X Y) (+ Y Y)) 0.30400002)))) (+ (+ X Y) (+ Y Y)) ))) (SIN (IFLTE (IFLTE Y (+ X Y) (- X Y) (+ Y Y) ) (* X X) (SIN (IFLTE (\% Y Y) (\% (SIN (SIN (\% Y 0.30400002))) X) (\% Y 0.30400002 ) (SIN (SIN (IFLTE (IFLTE (SIN (\% (SIN X) (+ -0.12499994 -0.15999997)) (\% X -0.10399997) (- X Y) (+ X Y)) (SIN (\% (SIN X) (+ -0.12499994 -
$0.15999997))$ ) (SIN (SIN (\% (SIN X) $(+-0.12499994-$
$0.15999997))$ )) (+ (+ X Y) (+ Y Y) )))))) $(\% \mathrm{Y}$ $0.30400002)$ )))

Figure 22 shows the fitness histograms for five different generations of the run. Each bar in the histogram represents a range of ten levels of fitness between 0 and 194. Note the undulating left-to-right movement of the fitness of the population over the generations.

Figure 22 Fitness histograms for generations 0, 12, and 36 of intertwined spirals problem.

If we retest the best-of-run individual from generation 36 on the two intertwined spirals with sample points chosen twice as dense, we find that 372 of the 388 points (i.e., $96 \%$ ) are correctly classified. And, if we retest with sample points that are ten times more dense, we find that 1,818 of the 1,940 points (i.e., $94 \%$ ) are still correctly classified.

Note that we did not pre-specify the size and shape of the solution to the problem. As we proceeded from generation to generation, the size and shape of the best-of-generation individuals changed. The structure of the S-expression emerged as a result of the selective pressure exerted by the fitness measure (i.e. number of fitness cases correctly classified).

## 8. Robotics - Box Moving Robot

In the box moving problem, an autonomous mobile robot must find a box located in the middle of an irregularly shaped room and move it to the edge of the room within a reasonable amount of time. Mahadevan and Connell [1991] reported on using reinforcement learning techniques in producing a program to control an autonomous mobile robot to perform this task in the style of the subsumption architecture [Brooks 1986, Connell 1990, Mataric 1990].

The robot has 12 sonar sensors which report the distance to the the nearest object (whether wall or box) as a floating point number in feet. The twelve sonar sensors (each covering $30^{\circ}$ ) together provide $360^{\circ}$ coverage around the robot.

The robot is able to move forward, turn right, and turn left. After the robot finds the box, it can move the box by pushing against it. However, this sub-task may prove difficult because if the robot applies force not coaxial with the center of gravity of the box, the box
will start to rotate. The robot will then lose contact with the box and will probably then fail to push the box to the wall in a reasonable amount of time.

The robot is considered successful if any part of the box touches any wall within the allotted amount of time.

The robot is capable of executing three primitive motor functions, namely, moving forward by a constant distance, turning right by $30^{\circ}$, and turning left by $30^{\circ}$. The three primitive motor functions MF , TR, and TL each take one time step (i.e., 1.0 seconds) to execute. All sonar distances are dynamically recomputed after each execution of a move or turn. The function TR (Turn Right) turns the robot $30^{\circ}$ to the right (i.e., clockwise). The function TL (Turn Left) turns the robot $30^{\circ}$ to the left (i.e., counter-clockwise). The function MF (Move Forward) causes the robot to move 1.0 feet forward in the direction it is currently facing in one time step. If the robot applies its force orthogonally to the midpoint of an edge of the box, it will move the box about 0.33 feet per time step.

The robot has a BUMP and a STUCK detector. We used a 2.5 foot wide box. The north (top) wall and west (left) wall of the irregularly shaped room are each 27.6 feet long.

The sonar sensors, the two binary sensors, and the three primitive motor functions are not labeled, ordered, or interpreted in any way. The robot does not know a priori what the sensors mean nor what the primitive motor functions do. Note that the robot does not operate on a cellular grid; its state variables assume a continuum of different values.

The first major step in preparing to use genetic programming is to identify the set of terminals. We include the 12 sonar sensors and the three primitive motor functions (each taking no arguments) in the terminal set. Thus, the terminal set T for this problem is
$T=\{S 00, S 01, S 02, S 03, \ldots, S 11, S S,(M F)$, (TR), (TL) $\}$.

The second major step in preparing to use genetic programming is to identify a sufficient set of primitive functions for the problem. The function set F consists of
$F=\{I F B M P, I F S T K$, IFLTE, PROGN2 $\}$.
The functions IFBMP and IFSTK are based on the BUMP detector and the STUCK detector defined by Mahadevan and Connell [1991]. Both of these functions take two arguments and evaluate their first argument if the detector is on and otherwise evaluates their second argument.

The iflte (If-Less-Than-or-Equal) function is a four-argument comparative branching operator that executes its third argument if its first argument is less than its second (i.e., then) argument and, otherwise, executes the fourth (i.e., else) argument. The operator

IFLTE is implemented as a macro in LISP so that only either the third or fourth argument is evaluated depending on the outcome of the test involving the first and second argument. Since the terminals in this problem take on floating point values, this function is used to compare values of the terminals. IFLTE allows alternative actions to be executed based on comparisons of observation from the robot's environment. IFLTE allows, among other things, a particular action to be executed if the robot's environment is applicable and allows one action to suppress another. It also allows for the computation of the minimum of a subset of two or more sensors. IFBMP and IFSTK are similarly defined as macros

The connective function PROGN2 taking two arguments evaluates both of its arguments, in sequence, and returns the value of its second argument.

Although the main functionality of the moving and turning functions lies in their side effects on the state of the robot, it is necessary, in order to have closure of the function set and terminal set, that these functions return some numerical value. For Version 1 only, we decided that each of the moving and turning functions would return the minimum of the two distances reported by the two sensors that look forward. Also, for Version 1 only, we added one derived value, namely the terminal SS (Shortest Sonar) which is the minimum of the 12 sonar distances $\mathrm{S} 0, \mathrm{~S} 1, \ldots, \mathrm{~S} 11$, in the terminal set T .

The third major step in preparing to use genetic programming is the identification of the fitness function for evaluating how good a given computer program is at solving the problem at hand.

The fitness of an individual S-expression is computed using fitness cases in which the robot starts at various different positions in the room. The fitness measure for this problem is the sum of the distances, taken over four fitness cases, between the wall and the point on the box that is closest to the nearest wall at the time of termination of the fitness case.

A fitness case terminates upon execution of 350 time steps or when any part of the box touches a wall. If, for example, the box remains at its starting position for all four fitness cases, the fitness is 26.5 feet. If, for all four fitness cases, the box ends up touching the wall prior to timing out for all four fitness cases, the raw fitness is zero (and minimal).

The population size is 500 here.

### 8.1 Version 1

Figure 23 shows the irregular room, the starting position of the box, and the starting position of the robot for the particular fitness case in which the robot starts in the southeast part of the room. The raw fitness of a majority of the individual S-expressions from generation 0 is 26.5 (i.e., the sum, over the four
fitness cases, of the distances to the nearest wall) since they cause the robot to stand still, to wander around aimlessly without ever finding the box, or, in the case of the individual program shown in the figure, to move toward the box without reaching it.

Even in generation 0, some individuals are better than others. Figure 24 shows the trajectory of the best-of-generation individual from generation 0 from one run. This individual containing 213 points finds the box and moves it a short distance for one of the four fitness cases, thereby scoring a raw fitness of 24.5.

Figure 23 Typical random robot trajectory from generation 0 .

Figure 24 Trajectory of the best-of-generation individual for generation 0 .

The Darwinian operation of fitness proportionate reproduction and genetic crossover (sexual recombination) is now applied to the population, and a new population of S-expressions is produced. Fitness progressively improved between generations 1 and 6 .

In generation 7, the best-of-generation individual succeeded in moving the box to the wall for one of the four fitness cases (i.e., it scored one hit). Its fitness was 21.52 and it had 59 points (i.e. functions and terminals) in its program tree.

By generation 22, the fitness of the best-ofgeneration individual improved to 17.55 . Curiously, this individual, unlike many earlier individuals, did not succeed in actually moving the box to a wall for any of the fitness cases.

By generation 35, the best-of-generation individual had 259 points and a fitness of 10.77 .

By generation 45 of the run, the best-of-generation individual computer program was successful, for all four fitness cases, in finding the box and pushing it to the wall within the available amount of time. Its fitness was zero. This best-of-run individual had 305 points.

Note that we did not pre-specify the size and shape of the solution to the problem. As we proceeded from generation to generation, the size and shape of the best-of-generation individuals changed. The number of points in the best-of-generation individual was 213 in generation 0,59 in generation 7, 259 in generation 35 , and 305 in generation 45 . The structure of the S expression emerged as a result of the selective pressure exerted by the fitness measure.

Figure 25 shows the trajectory of the robot and the box for the 305 -point best-of-run individual from generation 45 for the fitness case where the robot starts in the southeast part of the room. For this fitness case, the robot moves more or less directly toward the box and then pushes the box almost flush to the wall.

Figure 26 shows the trajectory of the robot and the box for the fitness case where the robot starts in the northwest part of the room. Note that the robot clips the southwest corner of the box and thereby causes it to rotate in a counter clockwise direction until the box is moving almost north and the robot is at the midpoint of the south edge of the box.

Figure 27 shows the trajectory of the robot and the box for the fitness case where the robot starts in the northeast part of the room. For this fitness case, the robot's trajectory to reach the box is somewhat inefficient. However, once the robot reaches the box, the robot pushes the box more of less directly toward the west wall.

Figure 28 shows the trajectory of the robot and the box for the fitness case where the robot starts in the southwest part of the room.

Figure 25 Trajectory of the best-of-run individual with the robot starting in the southeast.

Figure 26 Trajectory of the best-of-run individual with the robot starting in the northwest.

Figure 27 Trajectory of the best-of-run individual with the robot starting in the northeast.

Figure 28 Trajectory of the best-of-run individual with the robot starting in the southwest.

### 8.2 Version 2

In the foregoing discussion of the box moving problem, the solution was facilitated by the presence of the sensor SS in the terminal set and the fact that the functions MF, TL, and TR returned a numerical value equal to the minimum of several designated sensors. This is in fact the way we solved it the first time.

This problem can, however, also be solved without the terminal $S S$ being in the terminal set and with the three functions each returning a constant value of zero. We call these three new functions MF $0, \mathrm{TLO}$, and TRO. The new function set is $\mathrm{F}_{0}=\{\mathrm{MF} 0, \mathrm{TRO}, \mathrm{TL} 0$, IFLTE, PROGN2 $\}$. We raised the population size from 500 to 2,000 in the belief that version 2 of this problem would be much more difficult to solve.

In our first (and only) run of version 2 of this problem, an $100 \%$-correct S -expression containing

Figure 129 Hits histogram for generations 0, 15, and 20 for Version 2.

207 points with a fitness of 0.0 emerged on generation 20:

Figure 29 shows the hits histogram for generations 0,15 , and 20 . Note the left-to-right undulating movement of the center of mass of the histogram and the high point of the histogram. This "slinky" movement reflects the improvement of the population as a whole.

Koza and Rice [1992b] compares genetic programming with reinforcement learning in connection with this problem.

We have also employed genetic programming to evolve a computer program to control a wall following robot using the subsumption architecture [Koza 1992d] based on impressive work successfully done by Mataric [1990] in programming an autonomous mobile robot called TOTO.

## 9. Hierarchical Automatic Function Definition -11-Parity Function

A key goal in machine learning and artificial intelligence is to facilitate the solution of a problem by automatically and dynamically decomposing the problem into simpler subproblems.

When a human programmer writes a computer program to solve a problem, he often creates a subroutine (procedure, function) enabling a common calculation to be performed without tediously rewriting the code for that calculation. For example, if a programmer needed to write a program for Boolean parity functions of several different high orders, he might find it convenient first to write a
subroutine for some lower-order parity function. He would call on the code for this low-order parity function at different places and with different combinations of arguments from his main program and then combine the results in the main program to produce the desired higher-order parity function. Specifically, if a programmer were using the LISP programming language, he might first write a function definition for the odd-2-parity function xor (exclusive-or) as follows:
(defun xor ( $\arg 0 \arg 1$ )
(values ( $\operatorname{or}(\operatorname{and} \arg 0(n o t \arg 1))$ ( and (not $\arg 0) \arg 1))$ )).
This function definition (called a "defun" in LISP) does four things. First, it assigns a name, xor, to the function being defined thereby permitting subsequent reference to it. Second, this function definition identifies the argument list of the function being defined, namely the list (arg0 arg1) containing two dummy variables (formal parameters) called arg 0 and arg1. Third, this function definition contains a body which performs the work of the function. Fourth, this function definition identifies the value to be returned by the function. In this example, the single value to be returned is emphasized via an explicit invocation of the values function. This particular function definition has two dummy arguments, returns only a single value, has no side effects, and refers only to the two local dummy variables (i.e., it does not refer to any of the actual variables of the overall problem contained in the "main" program). However, in general, defined functions may have any number of arguments (including no arguments), may return multiple values (or no values), may or may not perform side effects, and may or may not explicitly refer to the actual (global) variables of the main program.

Once the function xor is defined, it may then be repeatedly called with different instantiations of its arguments from more than one place in the main program. For example, if the programmer needed the even-4-parity at some point in his main program, he might write

$$
(\text { xor }(\text { xor } \mathrm{d} 0 \mathrm{~d} 1)(\text { not }(\text { xor } \mathrm{d} 2 \mathrm{~d} 3))) .
$$

Function definitions exploit the underlying regularities and symmetries of a problem by obviating the need to tediously rewrite lines of essentially similar code. A function definition is especially efficient when it is repeatedly called with different instantiations of its arguments. However, the importance of function definition goes well beyond efficiency. The process of defining and calling a function, in effect, decomposes the problem into a hierarchy of subproblems.

The ability to extract a reusable subroutine is potentially very useful in many domains. Consider the problem of discovery of a neural network to recognize patterns presented as an array of pixels. Suppose the solution of a pattern recognition problem requires discovery of a particular feature (e.g., a line end)
within the 3 by 3 pixel region in the upper left corner of an 8 by 8 array of pixels and also requires discovery of that same feature within a 3 by 3 pixel region in the lower left corner of the overall array. Existing neural net paradigms can successfully discover the useful feature among the nine pixels $\mathrm{p}_{11}, \mathrm{p}_{12}, \mathrm{p}_{13}, \mathrm{p}_{21}, \mathrm{p}_{22}$, $\mathrm{p}_{23}, \mathrm{p}_{31}, \mathrm{p}_{32}, \mathrm{p}_{33}$ in the upper left corner of a 8 by 8 array of pixels and can independently rediscover the same useful feature among the nine pixels $p_{61}, p_{62}$, $\mathrm{p}_{63}, \mathrm{p}_{16}, \mathrm{p}_{71}, \mathrm{p}_{72}, \mathrm{p}_{73}, \mathrm{p}_{81}, \mathrm{p}_{82}, \mathrm{p}_{83}$ in the lower left corner of the overall array. But existing neural net paradigms do not provide a way to discover the common feature just once, to generalize the feature so that it is not rigidly expressed in terms of particular pixels but is parameterized by its position, and to then reuse the generalized feature detector to recognize occurrences of the feature in different 3 by 3 pixel regions within the array. That is, existing paradigms do not provide a way to discover a function of nine dummy variables just once and to call that function twice (once with $\mathrm{p}_{11}, \ldots, \mathrm{p}_{33}$ as arguments and once with $\mathrm{p}_{61}, \ldots, \mathrm{p}_{83}$ as arguments). Such an ability would amount to discovering a nine-input subassembly of neurons with appropriate weights, making a copy of the entire subassembly, implanting the copy elsewhere in the overall neural net, and then connecting nine different pixels as inputs to the subassembly in its new location in the overall neural net.

Hierarchical automatic function definition can be implemented within the context of genetic programming by establishing a constrained syntactic structure for the individual S-expressions in the population [Koza 1992a]. Each individual Sexpression in the population contains one (or more) function-defining branches and one (or more) "main" result-producing branches. The result-producing branch may call the defined functions. One defined function may hierarchically refer to another alreadydefined function (and potentially even itself), although such hierarchical or recursive references will not be used in this article.

### 9.1 Learning the Even-Parity Function without Hierarchical Automatic Function Definition

In order to establish the facilitating benefits of hierarchical automatic function definition in genetic programming, we first solve some benchmark problems without using hierarchical automatic function definition.

The Boolean even-parity function of $k$ Boolean arguments returns T (True) if an even number of its arguments are T , and otherwise returns NIL (False).

In applying genetic programming to the even-parity function of $k$ arguments, the terminal set T consists of the $k$ Boolean arguments D0, D1, D2, ... involved in the problem, so that

$$
\mathrm{T}=\{\mathrm{D} 0, \mathrm{D} 1, \mathrm{D} 2, \ldots\}
$$

The function set $F$ for all the examples herein consists of the following computationally complete set of four two-argument primitive Boolean functions:

$$
F=\{A N D, O R, N A N D, N O R\}
$$

The Boolean even-parity functions appear to be the most difficult Boolean functions to find via a blind random generative search of S-expressions using the above function set F and the terminal set T . For example, even though there are only 256 different Boolean functions with three arguments and one output, the Boolean even-3-parity function is so difficult to find via a blind random generative search that we did not encounter it at all after randomly generating $10,000,000$ S-expressions using this function set $F$ and terminal set $T$. In addition, the even-parity function appears to be the most difficult to learn using genetic programming using the function set F and terminal set T above [Koza 1992a].

In applying genetic programming to the problem of learning the Boolean even-parity function of $k$ arguments, the $2^{k}$ combinations of the $k$ Boolean arguments constitute an exhaustive set of fitness cases for learning this function. The standardized fitness of an S-expression is the sum, over these $2^{k}$ fitness cases, of the Hamming distance (error) between the value returned by the S-expression and the correct value of the Boolean function. Standardized fitness ranges between 0 and $2^{k}$; a value closer to zero is better. The raw fitness is equal to the number of fitness cases for which the S -expression is correct (i.e., $2^{k}$ minus standardized fitness); a higher value is better.

We first consider how genetic programming would solve the problems of learning the even-3-parity function (three-argument Boolean rule 105), the even-4-parity function (four-argument Boolean rule 38,505 ), and the even-5-parity function (fiveargument Boolean rule $1,771,476,585$ ). In identifying these $k$-argument Boolean functions in this way, we are employing a numbering scheme wherein the value of the function for the $2^{k}$ combinations of its $k$ Boolean arguments are concatenated into a $2^{k \text {-bit }}$ binary number and then converted to the equivalent decimal number. For example, the $2^{3}=8$ values of the even-3-parity function are $0,1,1,0,1,0,0$, and 1 (going from the fitness case consisting of three true arguments to the fitness case consisting of three false arguments). Since $01101001_{2}=105_{10}$, the even-3parity function is referred to as three-argument Boolean rule 105.

The terminal set T for the even-3-parity problem consists of

$$
\mathrm{T}=\{\mathrm{D} 0, \mathrm{D} 1, \mathrm{D} 2\}
$$

In one run of genetic programming using a population size of 4,000 (the value of $M$ used consistently in this section, except as otherwise noted),
genetic programming discovered the following S expression containing 45 points (i.e., 22 functions and 23 terminals) with a perfect value of raw fitness of 8 (out of a possible value of $2^{3}=8$ ) in generation 5 :
(AND (OR (OR D0 (NOR D2 D1)) D2) (AND (NAND (NOR (NOR D0 D2) (AND (AND D1 D1) D1)) (NAND (OR (AND D0 D1) D2) D0)) (OR (NAND (AND D0 D2) (OR (NOR D0 (OR D2 D0)) D1)) (NAND (NAND D1 (NAND D0 D1)) D2)))).
We then considered the even-4-parity function. In one run, genetic programming discovered the following S-expression containing 149 points with a perfect value of raw fitness of 16 (out of $2^{4}=16$ ) in generation 24:
(AND (OR (OR (OR (NOR D0 (NOR D2 D1)) (NAND (OR (NOR (AND D3 D0) D2) (NAND D0 (NOR D2 (AND D1 (OR D3 D2))))) D3)) (AND (AND D1 D2) D0)) (NAND (NAND (NAND D3 (OR (NOR D0 (NOR (OR D3 D2) D2)) (NAND (AND (AND (AND D3 D2) D3) D2) D3)) ) (NAND (OR (NAND (OR D0 (OR D0 D1)) (NAND D0 D1)) D3) (NAND D1 D3))) D3)) (OR (OR (NOR (NOR (AND (OR (NOR D3 D0) (NOR (NOR D3 (NAND (OR (NAND D2 D2) D2) D2)) (AND D3 D2))) D1) (AND D3 D0)) (NOR D3 (OR D0 D2))) (NOR D1 (AND (OR (NOR (AND D3 D3) D2) (NAND D0 (NOR D2 (AND D1 D0)))) (OR (OR D0 D3) (NOR D0 (NAND (OR (NAND D2 D2)
D2) D2))))) (AND (AND D2 (NAND D1 (NAND (AND D3 (NAND D1 D3)) (AND D1 D1)))) (OR D3 (OR D0 (OR D0 D1)))))).

Figure 30 presents two curves, called the performance curves, relating to the even-3-parity function over a series of runs. The curves are based on 66 runs with a population size $M$ of 4,000 and a maximum number of generations to be run $G$ of 51 .

The rising curve in figure 30 shows, by generation, the experimentally observed cumulative probability of success, $P(M, i)$, of solving the problem by generation $i$ (i.e., finding at least one S-expression in the population which produces the correct value for all $2^{3}$ $=8$ fitness cases). As can be seen, the experimentally observed value of the cumulative probability of success, $P(M, i)$, is $91 \%$ by generation 9 and $100 \%$ by generation 21 over the 66 runs.

Figure 30 Performance curves for even-3-parity function showing that it is sufficient to process 80,000 individuals to yield a solution with $99 \%$ probability with genetic programming.

The second curve in figure 30 shows, by generation, the number of individuals that must be processed, $I(M, i, z)$, to yield, with probability $z$, a solution to the problem by generation $i . \quad I(M, i, z)$ is
derived from the experimentally observed values of $P(M, i)$. Specifically, $I(M, i, z)$ is the product of the population size $M$, the generation number $i$, and the number of independent runs $R(z)$ necessary to yield a solution to the problem with probability $z$ by generation $i$. In turn, the number of runs $R(z)$ is given by

$$
R(z)=\left[\frac{\log (1-z)}{\log (1-P(M, i))}\right]
$$

where the square brackets indicates the ceiling function for rounding up to the next highest integer. The probability $z$ will be $99 \%$ herein.

As can be seen, the $I(M, i, z)$ curve reaches a minimum value at generation 9 (highlighted by the light dotted vertical line). For a value of $P(M, i)$ of $91 \%$, the number of independent runs $R(z)$ necessary to yield a solution to the problem with a $99 \%$ probability by generation $i$ is 2 . The two summary numbers (i.e., 9 and 80,000 ) in the oval indicate that if this problem is run through to generation 9 (the initial random generation being counted as generation 0 ), processing a total of 80,000 individuals (i.e., $4,000 \infty$ 10 generations $\infty 2$ runs) is sufficient to yield a solution to this problem with $99 \%$ probability. This number 80,000 is a measure of the computational effort necessary to yield a solution to this problem with $99 \%$ probability.

Figure 31 shows similar performance curves for the even-4-parity function based on 60 runs. The experimentally observed cumulative probability of success, $P(M, i)$, is $35 \%$ by generation 28 and $45 \%$ by generation 50 . The $I(M, i, z)$ curve reaches a minimum value at generation 28. For a value of $P(M, i)$ of $35 \%$, the number of runs $R(z)$ is 11 . The two numbers in the oval indicate that if this problem is run through to generation 28 , processing a total of $1,276,000$ (i.e., $4,000 \infty 29$ generations $\infty 11$ runs) individuals is sufficient to yield a solution to this problem with $99 \%$ probability.

Figure 31 Performance curves for even-4-parity function showing that it is sufficient to process 1,276,000 individuals to yield a solution with $99 \%$ probability with genetic programming.

Thus, according to this measure of computational effort, the even-4-parity problem is about 16 times harder to solve than the even-3-parity problem.

We are unable to directly extend this comparison of the computational effort necessary to solve the evenparity problem with increasing numbers of arguments
with our chosen population size of 4,000 . When the even-5-parity function was run with a population size of 4,000 and each run arbitrarily stopped at our chosen maximum number $G=51$ of generations to be run, no solution was found after 20 runs. (Solutions might well have been found if we had continued the run, but we did not do this). Even after increasing the population size to 8,000 (with $G=51$ ), we did not get a solution until our eighth run. This solution contained 347 points.

Notice that the structural complexity (i.e., the total number of function points and terminal points in the $S$ expression) of the solutions produced in these three cited runs dramatically increased with an increasing number of arguments (i.e. structural complexity was 45,149 , and 347 , respectively, above for the $3-, 4-$, and 5-parity functions).

The population size of 4,000 is undoubtedly not optimal for any particular parity problem and is certainly not optimal for all sizes of parity problems. Nonetheless, it is clear that learning the even-parity functions with increasing numbers of arguments requires dramatically increasing computational effort and that the structural complexity of the solutions become increasingly large.

### 9.2 Hierarchical Automatic Function Definition

The inevitable increase in computational effort and structural complexity for solving parity problems of order greater than four could be controlled if we could discover the underlying regularities and symmetries of this problem and then hierarchically decompose the problem into more tractable sub-problems. Specifically, we need to discover a function parameterized by dummy variables that would be helpful in decomposing and solving the problem.

If a human programmer were writing code for the even-3-parity or even-4-parity functions, he would probably choose to call upon either the odd-2-parity function (also known as the exclusive-or function XOR) or the even-2-parity function (also known as the equivalence function $E Q V$ ). If a human programmer were writing code for the even-5-parity function and parity functions with additional arguments, he would probably also want to call upon either the even-3parity (three-argument Boolean rule 105) or the odd-3parity (three-argument Boolean rule 150). These lower-order parity functions would greatly facilitate writing code for the higher-order parity functions. None of these low-order parity functions are, of course, in our original set F of available primitive Boolean functions.

The potentially helpful role of dynamically evolving useful "building blocks" in genetic programming has been recognized for some time [Koza 1990]. However, when we talk about "hierarchical automatic function definition" in this
article, we are not contemplating merely defining a function in terms of a sub-expression composed of particular fixed terminals (i.e., actual variables) of the problem. Instead, we are contemplating defining functions parameterized by dummy variables (formal parameters). Specifically, if the exclusive-or function XOR were being automatically defined during a run, it would be a version of XOR parameterized by two dummy variables (perhaps called ARGO and ARG1), not a mere call to XOR with particular fixed actual variables of the problem (e.g., D0 and D1). When this parameterized version of the XOR function is called, its two dummy variables ARGO and ARG1 would be instantiated with two specific values, which would either be the values of two terminals (i.e., actual variables of the problem) or the values of two expressions (each composed ultimately of terminals). For example, the exclusive-or function XOR might be called via (XOR D0 D1) on one occasion and via (XOR D2 D3) on another occasion. On yet another occasion, XOR might be called via
(XOR (AND D1 D2) (OR D0 D2)),
where the two arguments to XOR are the values returned by the expressions (AND D1 D2) and (OR D0 D2), respectively. Each of these expressions is ultimately composed of the actual variables (i.e., terminals) of the problem.

Moreover, when we talk about "automatic" and "dynamic" function definition, the goal is to dynamically evolve a dual structure containing both function-defining branches and result-producing (i.e., value-returning) branches by means of natural selection and genetic operations. We expect that genetic programming will dynamically evolve potentially useful function definitions during the run and also dynamically evolve an appropriate resultproducing "main" program that calls these automatically defined functions.

Note that many existing paradigms for machine learning and artificial intelligence do define functional subunits automatically and dynamically during runs (the specific terminology, of course, being specific to the particular paradigm). For example, when a set of weights are discovered enabling a particular neuron in a neural network to perform some subtask, that learning process can be viewed as a process of defining a function (i.e., a function taking the values of the specific inputs to that neuron as arguments and returning an output signal, perhaps a zero or one). Note, however, that the function thus defined can be called only once from only one particular place within the neural network. It is called only in the specific part of the neural net (i.e., the neuron) where it was created and it is called only with the original, fixed set of inputs to that specific neuron. Note also that existing paradigms for neural networks do not provide a way to re-use the set of weights discovered in that part of the network in other parts of the network where
a similar subtask must be performed on a different set of inputs. The recent work of Gruau [1992] on recursive solutions to Boolean functions is a notable exception.

### 9.3 Even-4-Parity Function

Hierarchical automatic function definition can be implemented within the context of genetic programming by establishing a constrained syntactic structure [Koza 1992a, Chapter 19] for the individual S-expressions in the population in which each individual contains one or more function-defining branches and one or more "main" result-producing branches which may call the defined functions.

The number of result-producing branches is determined by the nature of the problem. Since Boolean parity functions return only a single Boolean value, there would be only one "main" resultproducing branch to the S-expression in the constrained syntactic structure required.

We usually do not know a priori the optimal number of functions that will be useful for a given problem or the optimal number of arguments for each such function; however, considerations of computer resources (time, virtual memory usage, CONSing, garbage collection, and memory fragmentation) necessitate that choices be made. Additional computer resources are required for each additional function definition. There is a considerable increase in the computer resources required to support the ever-larger S-expressions associated with each larger number of arguments. There will usually be no advantage to having defined functions that take more arguments than there are terminals in the problem. When Boolean functions are involved, there is no advantage to evolving one-argument function definitions (since the only four one-argument Boolean functions and either in our function set already or constant-valued functions).

Thus, for the Boolean even-4-parity problem, it would seem reasonable to permit one two-argument function definition and one three-argument function definition within each S-expression. Thus, each individual S-expression in the population would have three branches. The first (leftmost) branch permits a two-argument function definition (defining a function called ADFO); the second (middle) branch permits a three-argument function definition (defining a function called ADF1); and the third (rightmost) branch is the result-producing branch. The first two branches are function-defining branches which may or may not be called upon by the result-producing branch.

Figure 32 shows an abstraction of the overall structure of an S-expression with two functiondefining branches and one result-producing branch. There are 11 "types" of points in each individual Sexpression in the population for this problem. The
first eight types are an invariant part of each individual S-expression.

The 11 types are as follows:
(1) the root (which will always be the place-holding PROGN function),
(2) the top point DEFUN of the function-defining branch for $A D F 0$,
(3) the name $A D F O$ of the function defined by this first function-defining branch,
(4) the argument list (ARGO ARG1) of ADF0,
(5) the top point DEFUN of the function-defining branch for ADF1,
(6) the name ADF1 of the function defined by this second function-defining branch,
(7) the argument list (ARGO ARG1 ARG2) of ADF1,
(8) the top point VALUES of the result-producing branch for the individual S -expression as a whole,
(9) the body of ADF 0 ,
(10) the body of ADF 1, and
(11) the body of the "main" result-producing branch.

Figure 32 Abstraction of the overall structure of an $S$ expression with two function-defining branches and the one result-producing branch.

Syntactic rules of construction govern points of types 9,10 , and 11 .

For points of type 9, the body of ADFO is a composition of functions from the given function set F and terminals from the terminal set A2 of two dummy variables, namely A2 $=\{$ ARG0, ARG1 $\}$.

For the points of type 10 , the body of $A D F 1$ is a composition of functions from the original given function set F along with ADF 0 and terminals from the set $A_{3}$ of three dummy variables, namely $A_{3}=$ \{ARG0, ARG1, ARG2\}. Thus, the body of ADF1 is capable of calling upon ADF 0 .

For the points of type 11, the body of the resultproducing branch is a composition of terminals (i.e., actual variables of the problem) from the terminal set $T$, namely $T=\{D 0, D 1, D 2, D 3\}$, as well as functions from the set $F_{3}$. $F_{3}$ contains the four original functions from the function set $F$ as well as the twoargument function $A D F O$ defined by the first branch and the three-argument function ADF1 defined by the second branch. That is, the function set $F_{3}$ is

$$
\begin{gathered}
\mathrm{F}_{3}=\{\mathrm{AND}, \mathrm{OR}, \mathrm{NAND}, \mathrm{NOR}, \mathrm{ADF} 0 \\
\mathrm{ADF} 1\}
\end{gathered}
$$

taking two, two, two, two, two, and three arguments, respectively. Thus, the result-producing branch is capable of calling the two defined functions ADFO and ADF1.

When the overall S-expression in figure 32 is evaluated, the PROGN evaluates each branch; however, the value(s) returned by the PROGN consists only of the value(s) returned by the VALUES function in the final result-producing branch.

Note that one might consider including the terminals from the terminal set $T$ (i.e., the actual variables of the problem) in the function-defining branches; however, we do not do so here.

In what follows, genetic programming will be allowed to evolve two function definitions in the function-defining branches of each S-expression and then, at its discretion, to call one, two, or none of these defined functions in the result-producing branch. We do not specify what functions will be defined in the two function-defining branches. We do not specify whether the defined functions will actually be used (it being, of course, possible, as we have already seen to solve this problem without any function definition by evolving the correct program in the result-producing branch). We do not favor one function-defining branch over the other. We do not require that a function-defining branch use all of its available dummy variables. The structure of all three branches is determined by the combined effect, over many generations, by the selective pressure exerted by the fitness measure and by the effects of the operations of Darwinian fitness proportionate reproduction and crossover.

Since a constrained syntactic structure is involved, we must create the initial random generation so that every individual S-expression in the population has the syntactic structure specified by the syntactic rules of construction presented above. Specifically, every individual $S$-expression must have the invariant structure represented by the eight points of types 1 through 8. Specifically, the bodies of ADF0 (type 9), ADF1 (type 10), and the result-producing branch (type 11) must be composed of the functions and terminals specified by the above syntactic rules of construction.

Moreover, since a constrained syntactic structure is involved, we must perform structure-preserving crossover so as to ensure the syntactic validity of all offspring as the run proceeds from generation to generation. Structure-preserving crossover is implemented by first allowing the selection of the crossover point in the first parent to be any point from the body of ADF0 (type 9), ADF1 (type 10), or the result-producing branch (type 11). However, once the crossover point in the first parent has been selected, the crossover point of the second parent must be of the same type (i.e., types 9,10 , or 11). This restriction on the selection of the crossover point of the second parent assures syntactic validity of the offspring.

### 9.4 Even-4-Parity Function

Each S-expression in the population for solving the even-4-parity function has one result-producing branch and two function-defining branches, each permitting the definition of one function of three dummy variables.

In one run of the even-4-parity function, the following $100 \%$-correct solution containing 45 points (not counting the invariant points of types 1 through 8 ) with a perfect value of 16 for raw fitness appeared on generation 4:
(PROGN (DEFUN ADF0 (ARG0 ARG1 ARG2)
(NOR (NOR ARG2 ARG0) (AND ARG0 ARG2)))
(DEFUN ADF1 (ARG0 ARG1 ARG2)
(NAND (ADF0 ARG2 ARG2 ARG0)
(NAND (ADF0 ARG2 ARG1 ARG2)
(ADF0 (OR ARG2 ARG1)
(NOR ARG0 ARG1)
(ADF0 ARG1 ARG0
ARG2)))))
(VALUES
(ADF0 (ADF1 D1 D3 D0) (NOR (OR D2 D3) (AND D3 D3)) (ADF0 D3 D3 D2)))).
The first branch of this best-of-run S-expression is a function definition establishing the defined function ADFO as the two-argument exclusive-or (XOR) function. The definition of $A D F 0$ ignores one of the available dummy variables, namely ARG1.

The second branch of the above S-expression calls upon the defined function $A D F 0$ (i.e., XOR) to define ADF1. This second branch appears to use all three available dummy variables; however, it reduces to the two-argument equivalence function EQV .

The result-producing (i.e., third) branch of this Sexpression uses all four terminals and both ADF 0 and ADF1 to solve the even-4-parity problem. This branch reduces to
(ADF0 (ADF1 D1 D0) (ADF0 D3 D2)).
which is equivalent to
(XOR (EQV D1 D0) (XOR D3 D2)).
That is, genetic programming decomposed the even-4-parity problem into two different parity problems of lower order (i.e., XOR and EQV).

Figure 33 shows the hierarchy (lattice) of function definitions used in this solution to the even-4-parity problem. Note also that the second of the two functions in this decomposition (i.e., EQV ) was defined in terms of the first (i.e., XOR).

Figure 33 Hierarchy (lattice) of function definitions.
Note that we did not specify that the exclusive-or XOR function would be defined in ADFO, as opposed to, say, the equivalence function, the if-then function, or any other Boolean function. Similarly, we did not specify what would be evolved in n ADF1. Genetic programming created the two-argument defined functions ADFO and ADF1 on its own to help solve this problem. Having done this, genetic programming then used ADFO and ADF1 in an appropriate way in the result-producing branch to solve the problem. Notice that the 45 points above are considerably fewer than the 149 points contained in the S -expression cited earlier for the even-4-parity problem.

Figure 34 presents the performance curves based on 23 runs for the even-4-parity with hierarchical automatic function definition. The cumulative probability of success $P(M, i)$ is $91 \%$ by generation 10 and $100 \%$ by generation 50 . The two numbers in the oval indicate that if this problem is run through to generation 10 , processing a total of 88,000 individuals (i.e., $4,000 \infty 11$ generations $\infty 2$ runs) is sufficient to yield a solution to this problem with $99 \%$ probability.

Figure 34 Performance curves for the even-4-parity problem show that it is sufficient to process 88,000 individuals to yield a solution with hierarchical automatic function definition.

### 9.5 Even 5-Parity Function

In one run of the even-5-parity problem, the following $100 \%$-correct solution containing 160 points with a perfect value of raw fitness of 64 emerged on generation 12:
(PROGN (DEFUN ADF0 (ARG0 ARG1 ARG2 ARG3)
(OR (OR (NOR (NOR ARG3 ARG1) (OR
ARG1 ARG3)) (AND (NAND ARG1 ARG3)
(NOR ARG1 ARG2))) (NAND (AND (OR

ARG1 ARG2) (NAND ARG1 ARG2)) (NAND ARG1 (AND (NOR ARG3 ARG1) ARG0)))))
(DEFUN ADF1 (ARG0 ARG1 ARG2 ARG3) (NAND (NAND (AND (NAND ARG1 ARG2)
(ADF0 ARG0 ARG3 ARG0 ARG2)) (NOR (NAND ARG3 ARG1) (AND ARG1 ARG1))) (AND (ADF0 ARG0 (NAND ARG1 ARG2) (ADF0 ARG3 ARG0 ARG3 ARG0) (AND ARG1 ARG1)) (ADF0 (ADF0 ARG3 ARG2 ARG3 ARG0) (ADF0 ARG0 ARG2 ARG2 ARG1) (ADF0 ARG3 ARG3 ARG3 ARG0) (NOR ARG3 ARG0)))))
(VALUES
(OR (OR (NOR (ADF0 D3 D1 D1 D3) (OR D0 D1)) (NOR (NAND D1 D2) (OR (OR D3 D2) (NOR D4 D4)))) (ADF1 (ADF1 D4 D0 D4 D1) (OR (OR (NOR (OR (NAND D1 D0) (ADF1 D1 D2 D3 D1)) (AND D4 D0)) D2) (NOR (OR (NAND D1 D0) (ADF1 D1 D2 D3 D1)) (AND D4 D0))) (NAND (ADF1 D1 D0 D0 D1) (NAND D0 D2)) (NAND (ADF1 D3 D4 D0 D0) (ADF0 D3 D1 D1 D3)))))).
The first branch is equivalent to the four-argument Boolean rule 50,115 , which is equivalent to (EQV ARG2 ARG1),
and which is an even-2-parity function that ignores two of the four available dummy variables.

The second branch is equivalent to the fourargument Boolean rule 38,250 , which is equivalent to (OR (AND (NOT ARG2) (XOR ARG3 ARG0))
(AND ARG2 (XOR ARG3 (XOR ARG1 ARG0)))).
Notice that this rule is not a parity function of any kind.

The result-producing (i.e., third) branch calls on defined functions $A D F O$ and $A D F 1$ and solves the problem.

The even 5-parity problem can be similarly solved with $99 \%$ probability with genetic programming using hierarchical automatic function definition by processing a total of 144,000 individuals.

### 9.6 Even 6- and 7-Parity Functions

The even 6 -, and 7 -parity problems can be similarly solved with $99 \%$ probability with genetic programming using hierarchical automatic function definition by processing a total of 864,000 , and 1,440,000 individuals, respectively.

### 9.7 Even 8-, 9-, and 10-Parity Functions

The $8-$ - $9-$, and 10 -parity problems can be similarly solved using hierarchical automatic function definition. Each problem was solved within the first four runs. We did not perform sufficient additional runs to compute a performance curve for these higher order parity problems.

For example, in one run of the even-8-parity function, the best-of-generation individual containing 186 points and attaining a perfect value of raw fitness of 256 appeared in generation 24. The first branch of this S-expression defined a four-argument defined function ADFO (four-argument Boolean rule 10,280). The second branch of this S-expression defined a fourargument defined function ADF1 (four-argument Boolean rule 26,214 ) which ignored two of its four arguments and is equivalent to
(XOR D0 D1).
In one run of the even-9-parity function, the best-of-generation individual containing 224 points and attaining a perfect value of raw fitness of 512 appeared in generation 40. The first branch of this S-expression defined a four-argument defined function ADF 0 (fourargument Boolean rule 1,872). The second branch of this S-expression defined a four-argument defined function ADF1 (four-argument Boolean rule 27,030) which is equivalent to the odd-4-parity function.

In one run of the even-10-parity function, the best-of-generation individual containing 200 points and attaining a perfect value of raw fitness of 1,024 appeared in generation 40 . The first branch of this Sexpression defined a four-argument defined function ADFO (four-argument Boolean rule 38,791). The second branch of this S-expression defined a fourargument defined function ADF1 (four-argument Boolean rule 23,205 ) which ignored one of its four arguments. This rule is equivalent to
(EVEN-3-PARITY D3 D2 D0).

### 9.8 Even-11-Parity Function

In one run of the even-11-parity function, the following best-of-generation individual containing 220 points and attaining a perfect value of raw fitness of 2,048 appeared in generation 21:
(PROGN (DEFUN ADF0 (ARG0 ARG1 ARG2 ARG3)
(NAND (NOR (NAND (OR ARG2 ARG1)
(NAND ARG1 ARG2)) (NOR (OR ARG1
ARG0) (NAND ARG3 ARG1))) (NAND
(NAND (NAND (NAND ARG1 ARG2) ARG1)
(OR ARG3 ARG2)) (NOR (NAND ARG2 ARG3) (OR ARG1 ARG3)))))
(DEFUN ADF1 (ARG0 ARG1 ARG2 ARG3)
(ADF0 (NAND (OR ARG3 (OR ARG0 ARG0))
(AND (NOR ARG1 ARG1) (ADF0 ARG1
ARG1 ARG3 ARG3)) (NAND (NAND (ADF0
ARG2 ARG1 ARG0 ARG3) (ADF0 ARG2
ARG3 ARG3 ARG2)) (ADF0 (NAND ARG3
ARG0) (NOR ARG0 ARG1) (AND ARG3
ARG3) (NAND ARG3 ARG0))) (ADF0
(NAND (OR ARG0 ARG0) (ADF0 ARG3
ARG1 ARG2 ARG0)) (ADF0 (NOR ARG0
ARG0) (NAND ARG0 ARG3) (OR ARG3
ARG2) (ADF0 ARG1 ARG3 ARG0 ARG0))
(NOR (ADF0 ARG2 ARG1 ARG2 ARG0)
(NAND ARG3 ARG3)) (AND (AND ARG2
ARG1) (NOR ARG1 ARG2)) (AND (NAND
(OR ARG3 ARG2) (NAND ARG3 ARG3)) (OR (NAND ARG3 ARG3) (AND ARG0 ARG0))))) (VALUES
(OR (ADF1 D1 D0 (ADF0 (ADF1 (OR (NAND D1 D7) D1) (ADF0 D1 D6 D2 D6) (ADF1 D6 D6 D4 D7) (NAND D6 D4)) (ADF1 (ADF0 D9 D3 D2 D6) (OR D10 D1) (ADF1 D3 D4 D6 D7) (ADF0 D10 D8 D9 D5)) (ADF0 (NOR D6 D9) (NAND D1 D10) (ADF0 D10 D5 D3 D5) (NOR D8 D2)) (OR D6 (NOR D1 D6))) D1) (NOR (NAND D1 D10) (ADF0 (OR (ADF0 D6 D2 D8 D4) (OR D4 D7)) (NOR D10 D6) (NOR D1 D2) (ADF1 D3 D7 D7 D6)))))).
The first branch of this S-expression defined the four-argument defined function ADF 0 (four-argument Boolean rule 50,115 ) which ignored two of its four arguments. ADFO is equivalent to the even-2-parity function, namely
(EQV ARG1 ARG2).
The second branch defined a four-argument defined function ADF1 which is equivalent to the even-4-parity function.

Substituting the definitions of the defined functions $A D F O$ and ADF1, the result-producing (i.e., third) branch becomes the program shown below.

```
(OR (EVEN-4-PARITY
    D1
    D0
    (EVEN-2-PARITY
        (EVEN-4-PARITY
            (EVEN-2-PARITY D3 D2)
            (OR D10 D1)
            (EVEN-4-PARITY D3 D4 D6 D7)
            (EVEN-2-PARITY D8 D9))
            (EVEN-2-PARITY (NAND D1 D10)
                            (EVEN-2-PARITY D5 D3)))
    D1)
(NOR (NAND D1 D10)
        (EVEN-2-PARITY (NOR D10 D6)
                            (NOR D1 D2))))
```

which is equivalent to the target even-11-parity function. Note that the even-2-parity function (ADF 0 ) appears six times in this solution and that the even-4parity function (ADF1) appears three times. Note that this entire solution for the even-11-parity function contains only 220 points (compared to 347 points for the solution to the mere even-5-parity without hierarchical automatic function definition).

Figure 35 shows the simplified version of the result-producing branch of this best-of-run individual for the even-11-parity problem. As can be seen, the even-11-parity problem was decomposed into a composition of even-2-parity functions and even-4parity functions.

Figure 35 The best-of-run individual from generation 21 of one run of the even-11-parity problem is a composition of even-2-parity and even-4-parity functions.

We found the above solution to the even-11-parity problem on our first completed run. The search space of 11-argument Boolean functions returning one value is of size $2^{2,048} \sim 10^{616}$. The even-11-parity problem was solved by decomposing into parity functions of lower orders.

### 9.9 Summary of Hierarchical Automatic Function Definition

Thus, the problem of learning various higher order even-parity functions can be solved with the technique of hierarchical automatic function definition in the context of genetic programming. Moreover, as can be seen in table 2, the technique of hierarchical automatic function definition facilitates the solution of these problems. That is, when problems are decomposed into a hierarchy of function definitions and calls, many fewer individuals must be processed in order to yield a solution to the problem. Moreover, the solutions discovered are comparatively smaller in terms of their structural complexity.

Table 2 Number of individuals $\mathrm{I}(\mathrm{M}, \mathrm{i}, \mathrm{z})$ required to be processed to yield a solution to various even-parity problems with $99 \%$ probability - with and without hierarchical automatic function definition.

| Size of parity <br> function | Without hierarchical <br> automatic function <br> definition | With hierarchical <br> automatic function <br> definition |
| :---: | :---: | :---: |
| 3 | 80,000 |  |
| 4 | $1,276,000$ | 88,000 |
| 5 |  | 144,000 |
| 6 |  | 864,000 |
| 7 |  | $1,440,000$ |

Automatic function definition has also been applied to the problem of discovery of impulse response functions [Koza, Keane, and Rice 1993].

## 10. Additional Examples of Genetic Programming

Genetic programming can be applied in many additional problem domains, including the following:

- evolution of a subsumption architecture for controlling a robot to follow walls or move boxes [Koza 1992d, Koza and Rice 1992b],
- discovering inverse kinematic equations to control the movement of a robot arm to a designated target point,
- emergent behavior (e.g., discovering a computer program which, when executed by all the ants in an ant colony, enables the ants to locate food, pick it up, carry it to the nest, and drop pheromones along the way so as to recruit other ants into cooperative behavior),
- symbolic integration, symbolic differentiation, and symbolic solution to general functional equations (including differential equations with initial conditions),
- planning (e.g., navigating an artificial ant along a trail, developing a robotic action sequence that can stack an arbitrary initial configuration of blocks into a specified order),
- generation of high entropy sequences of random numbers,
- induction of decision trees for classification,
- optimization problems (e.g., finding an optimal food foraging strategy for a lizard),
- sequence induction (e.g., inducing a recursive computational procedure for generating sequences such as the Fibonacci sequence),
- automatic programming of cellular automata,
- finding minimax strategies for games (e.g., differential pursuer-evader games, discrete games in extensive form) by both evolution and co-evolution,
- automatic programming (e.g., discovering a computational procedure for solving pairs of linear equations, solving quadratic equations for complex roots, and discovering trigonometric identities), and
- simultaneous architectural design and training of neural networks [Koza and Rice 1991].
Additional information and examples can be found in Koza [1992a].

## 11. Conclusions

We have shown that many seemingly different problems in machine learning and artificial intelligence can be viewed as requiring the discovery of a computer program that produces some desired output for particular inputs. We have also shown that the recently developed genetic programming paradigm described herein provides a way to search for a highly fit individual computer program. The technique of hierarchical automatic function definition can facilitate the solution of problems.

## 12. Acknowledgements

Christopher Jones prepared the figures for the econometric problem. James P. Rice of the Knowledge Systems Laboratory at Stanford University created all the other figures in this article and did some or all of the computer programming on a Texas Instruments Explorer computer for various problems in this article.
